Abstract

This paper studies the expansion of dollar store chains in the U.S. since 2008, which has generated public interest in their impact on retail markets and food accessibility. We show evidence that dollar store chains compete strongly with the grocery segment and find that their expansion has led to a large decline in the number of grocery stores and a significant reduction in fresh produce consumption for households with low income and high travel costs. We estimate a dynamic game of retail competition to understand the sources of dollar store success and calculate the cumulative effects of dollar store expansion.

Keywords: retail industry, dollar store, food access, dynamic games

The findings and conclusions in this paper have not been formally disseminated by the U.S. Department of Agriculture (USDA) and should not be construed to represent any agency determination or policy. The analysis, findings, and conclusions expressed in this paper also should not be attributed to Circana. This research was conducted in collaboration with USDA under a Third Party Agreement with Circana. All estimates and analyses in this paper based on Circana, Inc. data are by the authors and not by Circana, Inc.

1 Introduction

The growth of large chain retailers over the past several decades has transformed the retail sector in the United States, with implications for competition, labor markets, and aggregate outcomes such as inflation and productivity. A more recent and less studied phenomenon is the broad and dramatic rise of the dollar store retail format. Following previous waves of growth by large retail chains, the three main dollar store chains (Dollar General, Dollar Tree, and Family Dollar) have, in many ways, become the dominant mode of retailer in many markets, impacting competition, affordability, convenience, and food accessibility for a significant portion of the population.

The distinguishing features of these chains are the use of single or limited price points, particularly selling most goods for \$1, and assortments consisting of small serving-size basic consumables, clearance or irregular goods, and a lack of fresh produce. Beginning in the 1950s, these chains exhibited slow but steady growth over the decades that followed, establishing themselves primarily in small towns in rural areas. Following the 2008 recession, the growth of this format has been and continues to be exceptionally rapid.¹ In 2021, there were more of these stores operating than all the Walmarts, CVS, Walgreens, and Targets combined by a large margin. During the period 2018-2021, roughly half of all retail stores that opened in the U.S. were dollar stores.

The growth of dollar store chains has raised a number of policy issues: in particular, many local policymakers have expressed concerns that the rapid entry of dollar store chains in their cities has forced out local independent retailers, including neighborhood grocery stores. The latter may be especially concerning to the extent it reduces access to produce and other perishable food items for low-income residents, creating “food deserts.” These concerns and others have led many localities to ban dollar store chains from entering or pass dispersal regulations limiting their store density.²

Broadly speaking, the arguments for and against dollar store chains fall along these lines. Proponents argue that they introduce additional choice into underserved retail markets and that their strategy of entering in low-rent areas and opening multiple stores in the same market results in greater convenience for customers who can make short trips for specific items rather than long trips to the nearest big box store, which could be a large distance away.

¹The top three chains were collectively opening stores at the rate of 3.75 stores a day over the past decade (authors’ calculations).

²A partial list of cities that have banned dollar store entry or passed ordinances restricting the number of dollar stores that may enter includes: Birmingham AL, Atlanta GA, New Orleans LA, Akron OH, Oklahoma City OK, Tulsa OK, and Fort Worth TX. See <https://ilsr.org/rule/dollar-store-dispersal-restrictions/>

Opponents maintain that the aggressive entry strategy of dollar store chains has caused the exit of local independent retailers and prevented the entry of other retailers. Even if consumers value the convenience of the dollar stores, their strategy of offering basic consumables and household products efficiently using a low fixed cost model and avoiding the costly and complex provision of perishable food results in them capturing a large share of nearby grocers' profits. This could leave grocers unprofitable on the basis of food sales alone and potentially lead to exit, reducing convenient access to fresh produce and exacerbating nutritional inequality. Yet despite the extensive public and policy debate surrounding these issues, the academic literature has yet to study these claims or the broader effects of dollar store chain expansion.

In this paper, we provide new empirical evidence on the core issues in this policy debate. Our primary research questions are the following: why has the dollar store retail model been so successful and grown so rapidly? What has been the effect of dollar store expansion on local retail markets? Downstream of market structure, what has been the effect on consumer spending, particularly on fresh or perishable food? What would be the effect of the proposed policies limiting dollar store growth, if implemented more widely? For each of these questions, we go beyond average effects and analyze distributional impacts.

We leverage data from several sources. We track the number and type of retail stores, including dollar stores, across the U.S. using the Supplemental Nutrition Assistance Program (SNAP) Retailer panel, a yearly panel of SNAP-authorized retailers from 2008 to 2019. An advantage of this dataset is that it covers small independent retail stores, which are typically absent from other retail census used in the literature. We combine this with data on dollar store distribution center locations and opening dates, as well as data from Nielsen TDLinx on average per-store revenue. Finally, we match the data on store openings and closings to the Circana (previously named IRI) Consumer Network panel, which contains household-level data on all retail purchases for a large nationwide sample of consumers.

We first use an event study design to study the effects of dollar store entries on local market structure. We control for market-level demographics and demographic trends, as well as market-year fixed effects, and consistently find that dollar store entries are associated with a significant decrease in the number of independent grocery stores.³ The effect size is roughly the loss of one grocery store for every three dollar stores when measured in the area

³We follow the definition of “grocery stores,” which are distinct from “supermarkets and supercenters” in the USDA SNAP panel. Grocery stores are store primarily focused on selling food and consumable products, carry all four staple food categories, have annual revenue below \$2m, and are generally independently owned. Supermarkets/centers have annual revenue above \$2m, carry all four staple food categories, are part of a retail chain, and typically have ten or more checkout lanes with registers, bar code scanners, and conveyor belts.

0-2 miles around the entry location. In the area 2 to 5 miles away, the effect size becomes substantially smaller, suggesting the effects are local. The previous literature on the market structure effects of retail chain expansion has shown that big box chains such as Walmart do not compete intensely with local grocery stores due to vertical differentiation and their spatial distribution (Ellickson and Grieco (2013)). Our results suggest that dollar stores' vertical positioning and spatial pattern of entry, by contrast, have led to large negative effects on grocery stores.

When studying how consumer shopping behavior changes with dollar store entry, we find that households shift a share of their purchases away from grocery and convenience stores to the dollar stores. Households also decrease their spending (and volumes purchased) on produce by modest but significant amounts (4% to 7.3%), an effect that is increasing in the number of dollar store entries and acts in part through grocery store exits. This average effect masks important heterogeneity across households: low-income households (annual income less than \$45,000) and households with high travel costs (proxied by vehicle access) experience large declines in fresh produce spending (around 15%) whereas high income households (annual income above \$70,000) are not affected. This reduction in spending due to dollar store entry explains between 13% and 27% of the difference in fresh produce spending between high and low income households. By contrast, we do not find evidence that dollar stores lead to significant changes in spending on other food categories (e.g., canned produce, dairy, meats).⁴

Next, we estimate a dynamic structural model of the entry and exit choices of dollar store chains and their local competitors during the period of rapid expansion. The purpose of this model is to generate two additional sets of findings. First, it provides estimates of the size of dynamic entry and investment costs, as well as the competitive effects between different store formats. This enables us to explore various explanations for the success of the dollar store model. Second, the model allows us to evaluate how retail markets would evolve in the absence of dollar store expansion, such as under proposed entry regulation policies. We quantify the cumulative reduction in the number of grocery and convenience stores resulting from dollar store chain expansion across different market types, as well as the impact on consumer outcomes that are central to the current policy debate, e.g. travel costs and fresh produce spending. We do not explicitly weigh the various measures of consumer-level outcomes against each other in a unified framework to attempt a calculation of net consumer welfare. Doing so properly would require an additional structural model of both

⁴Our results complement earlier work on “food deserts,” such as Allcott et al. (2019), who find limited impacts from grocery store entries on produce purchases of nearby households. We find consistent results on grocery store entries, but much larger (negative) impacts from grocery exits, suggesting an asymmetry in how different changes to market structure impact consumer behavior.

store choice and category-level spending choices that also incorporates travel costs and the long-run impacts of different nutritional choices.

We model each store type’s entry and exit decisions as a dynamic oligopoly game following [Ericson and Pakes \(1995\)](#) but with a spatial component along the lines of [Seim \(2006\)](#). The key challenges in modeling this game in a tractable way are the complex nature of spatial competition and the dynamics that result from the growth over time in dollar stores’ distribution networks, which reduces their fixed store operating costs.

We take advantage of the fact that firms face a terminal choice when deciding whether or not to exit, which generates a type of finite dependence ([Arcidiacono and Miller \(2011\)](#), [Arcidiacono and Miller \(2019\)](#)). This property simplifies estimation of the game substantially as it allows us to represent the firms’ value functions directly in terms of the period-ahead probability of making the terminal choice. We leverage this property and estimate the model using the linear IV strategy of [Kalouptzidi et al. \(2020\)](#). The latter paper combines insights from the finite dependence approach and the GMM-Euler approach of [Aguirregabiria and Magesan \(2018\)](#) to propose a method (ECCP) that circumvents integration over the high-dimensional state space. As a methodological contribution, we extend the ECCP estimator from single-agent problems to dynamic games, highlighting and addressing an important selection problem arising in games, and apply it in our setting with long-lived chain entrants.

Our estimation results show that dollar store chains have significantly lower costs of opening a new store than their independent rivals, and are substantially more profitable. Grocery and convenience stores suffer substantial losses when located within 0-2mi of a dollar store. Estimates also point to strong demand cannibalization within chains in the 0-2mi radius. Further, dollar stores tend to benefit from scale economies when locating stores in moderate proximity (2-5mi radius), likely working through lower operating costs. The growth in dollar stores’ network of distribution centers leads to a reduction in store operating costs over our sample period. The results suggest that dollar stores are able to enter cheaply and operate with low fixed costs (increasingly so over time) due to store-level economies of density, a larger network of distribution centers, and not offering perishable produce. By focusing sales on high-margin consumables, they are particularly harmful to nearby grocery stores who are left selling mostly low-margin produce with high operating costs.

We use these estimates to evaluate the impact on local market structure of post-2010 dollar store expansion, as if local anti-dollar store policies were widely adopted. We find that, in the counterfactual scenario, markets would experience a 54% increase in the number of grocery stores (e.g., on average 1.65 grocery stores per market as compared to just over 1 in the factual scenario) and a 47% increase in the number of convenience stores.

We examine the distributional effects of these changes by controlling for market heterogeneity. The largest impacts on the number of grocery stores materialize in lower-income markets, those with larger shares of minority populations, those with higher poverty rates, and fewer households with access to a vehicle. Grocery store access improves substantially, with the median distance to the nearest store falling from 2.4 miles to 1.5 miles. By contrast, dollar store access would change relatively little due to their widespread entry prior to 2010. Finally, we combine our earlier reduced-form results on the impact of changes in market structure on produce spending with the structural results on the net impact of dollar store expansion. We find that low-income markets would, on net, purchase 6-9% more fresh produce in this counterfactual.

Related Literature. This paper contributes to three lines of research in economics. The first is the study of the evolution of the U.S. discount retail sector. This literature has focused on the impact of big box retailers (e.g., Walmart, K-Mart) and the supercenter format on market structure and competition (Jia (2008), Zhu and Singh (2009), Basker and Noel (2009), Igami (2011), Ellickson and Grieco (2013), Grieco (2014)), on labor markets (Basker (2005)), and the role of chain and density economies (Holmes (2011), Ellickson et al. (2013)). A key finding in this literature is that Walmart’s entry primarily harmed larger chain retailers in the local area within two miles of entry (Ellickson and Grieco (2013)). Small local retailers were not substantially harmed due to travel costs and horizontal and vertical differentiation between firms. Our results suggest that, whereas small local retailers were not in direct competition with big-box retailers like Walmart, the dollar store format is more of a direct competitor to these stores and has had a large impact on local retail markets as a result. The rise of the dollar store format, therefore, has a distinctive impact on retail and raises unique policy questions.

Our findings are in line with recent and emergent work studying the dollar store format: Feng et al. (2023) show that, despite their limited food assortments, dollar stores represent a growing share of food purchases especially in small markets. Chenarides et al. (2021) find that dollar store entry in a food desert area increases the likelihood that it remains a food desert; Lopez et al. (2023) show that dollar store entry is associated with grocery store exit, lower retail employment and sales, with these effects being larger in rural communities. In concurrent work, Chenarides et al. (Forthcoming) study the impact of dollar store expansion using a dynamic model of entry and data from Texas. They find that dollar stores benefit supermarkets by displacing the competitive fringe of small independent retailers. Their approach differs from ours as they assume stationarity, model spatial differentiation as a choice of market-level store density (rather than location choices), and do not consider households’ shopping behavior. In subsequent work, Schneier et al. (2023) investigates the effects of

the first dollar store entry in a zipcode on prices paid and basket size. [Cao \(2022\)](#) studies the welfare implications of dollar stores' entry via increased retail variety and supply of private-label products. Both papers rely on a representative household demand model with a single-unit discrete choice nested logit or nested CES preferences (respectively) and find moderate welfare gains from lower prices and increased retail and product variety. These papers do not consider the endogenous responses of rival stores and, importantly, changes in consumer travel costs, which are a first-order determinant of store choice ([Marshall and Pires \(2018\)](#)).

Second, this paper is related to the study of consumers' grocery shopping behavior and food accessibility. There is an extensive literature studying nutritional inequality in the U.S., with studies focusing on price-, access-, and nutrition education-based interventions ([Levi et al. \(2019\)](#)). Studies of food access have focused on introduction of grocery stores to markets designated as "food deserts," with case studies around individual store entries having found mixed results ([Cummins et al. \(2005\)](#), [Cummins et al. \(2014\)](#), [Elbel et al. \(2015\)](#), [Dubowitz et al. \(2015\)](#), [Liese et al. \(2014\)](#), [Rose and Richards \(2004\)](#), [Ver Ploeg and Rahkovsky \(2016\)](#), [Weatherspoon et al. \(2013\)](#).) Notably, [Allcott et al. \(2019\)](#) study a large number of grocery store and supermarket entries and find they have only small effects on the nutrition of nearby consumers and that nutritional inequality in the U.S. is largely explained by demand factors rather than limited food access, with differences in access and prices, explaining only about 10% of nutritional inequality. [Levi et al. \(2020\)](#) find that access to grocery stores impacts fruit and vegetable spending by affecting shopping frequency, but only among households with a low value of nutrition and at distances of less than 1 mile. [Hristakeva and Levine \(2022\)](#) leverage hurricane-induced temporary grocery store closures to detect supply-side effects and find that households affected by these closures shift the location and nutritional value of their purchases for a substantial period of time even after the grocery store has reopened. [Byrne et al. \(2022\)](#) study the effect of SNAP participation by retailers on consumers' shopping behavior and participating stores' inventory and revenue. They find that new SNAP retailers have a limited inventory of foods (e.g., no fresh produce) and do not significantly impact SNAP-eligible households' nutritional choices or prices paid in the 6 months following adoption.

We contribute to this literature by studying large numbers of dollar store and grocery store entry events, as well as large numbers of grocery store exits, to measure the impact of these events on households' shopping behavior, including spending on produce. We find results consistent with previous research (e.g., [Allcott et al. \(2019\)](#)) that entry of a grocery store or supermarket has a limited impact on shopping behavior and nutritional choices, but we depart from this literature in that we find that the exit of existing grocery stores and

the entry of large numbers of dollar stores do have significant impacts on food purchases. If consumers' shopping behavior is characterized by inertia or habit persistence, as suggested by the store choice literature in marketing (Ho et al. (1998)), this could generate asymmetric effects between grocery store openings and closings. Our results are therefore consistent with other work (e.g. Dubois et al. (2014)) finding that the supply side has a meaningful impact on nutritional outcomes.

Finally, this paper is related to the literature using dynamic games to study the market structure impacts of retail chains (Arcidiacono et al. (2016), Zheng (2016), Igami and Yang (2016), Hollenbeck (2017), Beresteanu et al. (2019), Fang and Yang (2022)). We depart from the existing literature in two ways. First, we account for the fact that over the sample period, dollar store chains have been growing their networks of distribution centers; incorporating this dynamic aspect of the industry is clearly important to better match observed entry patterns. Second, most previous dynamic game studies (Zheng (2016) being an exception) abstract from the spatial nature of retail competition. Because retail location choices are crucial in shaping the competitive environment (Ellickson et al. (2020)), we model firms' entry decisions into spatially differentiated locations as in Seim (2006) and Datta and Sudhir (2013).

The rest of the paper proceeds as follows: Section 2 describes the data and institutional details and provides descriptive statistics. Section 3 presents reduced-form static and dynamic event study results for the impact of dollar store entry on local market structure and consumers' shopping behavior. Section 4 introduces the dynamic entry and exit game. Section 5 discusses our market definition and the identification and estimation of the dynamic game. Section 6 shows the estimation results. Section 7 presents the counterfactual analysis. Section 8 concludes.

2 Industry Background, Data, and Descriptive Statistics

In this section, we describe the history and nature of the dollar store chains, present our data sources, and provide some descriptive statistics on the industry.

Dollar General originated the dollar store concept in 1955, selling a wide selection of low-cost basic goods at a single \$1 price point. The format became popular and a number of competing variety retailers adopted it, including Family Dollar, founded in 1959. Through decades of steady growth and consolidation among competing chains, by the 2000s there remained three major dollar store chains: Dollar General, Family Dollar, and Dollar Tree.

These chains distinguish themselves from other retailers by offering low prices in the form of a single price point or a limited number of round number price points.

Unlike other discount retailers like Aldi, they do not achieve their discounts by offering small selections and a large share of private labels. Instead, they offer moderately sized selections and a mix of major brand products and private labels.⁵ The stores are built in the 8,000-12,000 sq ft range and carry 10,000-12,000 SKUs. They also save costs by employing few employees and not offering fresh produce. They primarily sell basic consumables in small formats, seasonal products, and irregular or outdated products off-loaded by major brands. Another distinguishing feature is their market entry strategy, with a focus on small and low income markets under-served by big box retailers. We discuss these markets in greater detail below.

The dollar store chains have grown rapidly over the past several decades, particularly so after the recession of 2008. By 2021, Family Dollar operated roughly 7,100 stores, Dollar General operated 18,000 stores, and Dollar Tree owned 4,350 stores. The combined nearly 30,000 stores are substantially more than the number of Wal-Marts (5,300 stores), Targets (1,900 stores), CVS (9,900 stores), and Walgreens (9,300 stores) combined and is significantly larger than the number of Subway restaurants (21,000 restaurants), the largest U.S. restaurant chain and is similar to the number of Starbucks locations worldwide. The three chains earned a combined \$47 billion in revenue in 2019.

In 2015, the two smaller chains, Dollar Tree and Family Dollar, merged citing several potential complementarities between the two businesses: e.g., targeting broader ranges of customers, optimizing their combined real estate portfolio, exploiting synergies in sourcing, procurement, and distribution networks.⁶ Nonetheless, integration of the two chains has been slow over the following years: the two chains have continued to be run independently, both from a store operations and supply chain perspective. For example, store support centers were not consolidated by 2019, and distribution networks were largely run independently until 2020 (Dollar Tree (2018) and Figure A6).⁷ This motivates our treatment of the two chains as separate over our sample period ending in 2019.

Data: We combine several data sources to study dollar store expansion and the effects on consumers and local market structure.

The first is the SNAP Retailer panel, a yearly panel of SNAP-authorized retailers from 2008 to 2019. This dataset contains information on over 400,000 U.S. retailers including

⁵For instance, private labels represented 12% of Dollar General’s merchandise mix (Shih et al. (2019)).

⁶“Dollar Tree completes acquisition of Family Dollar.” Dollar Tree, Press Release, July 6, 2015.

⁷In 2020, two new distribution centers were opened serving both banners, e.g., Ocala, FL, and Rosenberg, TX.

their chain affiliation and store type, as well as small independent retailers. The SNAP retailer panel contains any store that accepts SNAP benefits. In addition to dollar stores, this includes convenience stores, combination stores (stores selling a combination of general merchandise and food products), grocery stores, drugstores, gas stations, supermarkets, and supercenters. We use the store type variable provided in the SNAP Retailer panel (rather than the store name) to classify stores by type (e.g., dollar, grocery, convenience store). Table 1 shows store counts by type in the SNAP panel. As far as we know, the SNAP retailer data is novel in the economics literature.⁸ The primary benefits of this public data source are that it is an annual measure and contains nearly the full universe of retailers in this industry. Crucially for this study, the panel includes small independent stores, which are typically absent from other retail census data used in the literature.

A drawback of this dataset is that entry into the SNAP program may not necessarily indicate the start of operation of a physical store. In particular, as the SNAP program debuted in 2008, there may have been delays in stores joining the program for the first few years. We alleviate this concern in two ways. For chains, we can compare store counts in the SNAP panel against publicly disclosed store counts in chains’ annual reports to investors. We do not find any significant discrepancies between the two sources. For independent stores, this approach is not possible: instead, we drop the first few years in the sample and restrict our analysis to the period from 2010 to 2019.

Table 1: Number of SNAP retailers by type (all U.S.)

Store type	Number of stores
Grocer	65,240
Supermarket/center	51,695
Small retail	283,140
<i>Combination Grocery/Other</i>	78,174
<i>Convenience Store</i>	204,966

Note: Combination grocery/Other includes dollar stores and drug stores. Convenience stores include gas stations.

We also compile data from the Circana Consumer Network panel, which we complement with the Circana MedProfiler dataset.⁹ The Consumer Network data contains household-

⁸The dataset has been used in the geography literature studying retail proximity (e.g., [Shannon et al. \(2018\)](#)).

⁹The Circana Consumer Network household panel data come from the National Consumer Panel (NCP), a joint venture between Circana and Nielsen to collect consumer data to provide consumer and marketing insights. For more background about the history and applications of scanner data in economics research, see [Dubois et al. \(2022\)](#).

level panels on all retail purchases for a nationwide sample of consumers. The MedProfiler data contain nutritional information for food purchases (e.g., sugar, sodium) and consumer health metrics (e.g., BMI). We observe the census tract a household resides in, which is more precise than other scanner datasets (e.g. Nielsen Homescan provides the household’s zipcode). This allows us to conduct our analysis at a more granular geographic level and construct more precise measures of retail proximity. Although the household scanner data is standard in the IO literature, we include informative summary statistics of spending by retail channel and food category in [Table A2](#) of the Appendix.¹⁰ These statistics show that spending at dollar stores is relatively low compared to other retail channels (e.g., supermarkets, supercenters). The largest expenditure share at dollar stores is for soda, snacks, candy, and crackers; whereas fresh produce spending is close to zero.¹¹

Finally, we collect market-level data on demographic characteristics from the Census and ACS at the census tract level. This allows us to study how market characteristics and consumer demographics affect dollar stores and other retailers’ entry behavior and profits. We also collect data on distribution centers of dollar store chains over time, namely the locations and opening dates for the three major chains.

[Figure 1](#) shows the total number of stores at the national level over the period 2010-2019. The total number of stores operated by the three major dollar store chains increases by 12,870 during this period. This increase is the net effect of 14,554 store entry events and 1,684 store exit events. The number of independent retail stores also increases, with this growth driven by convenience stores (71,010 store entries and 42,363 store exits). The number of grocery stores falls by 13% from its high in 2012.

We present the evolution of dollar store chains’ distribution centers over time, in [Figure A5](#) of the Appendix. Between 2000 and 2020, the number of distribution centers increases substantially from 14 to 42. This leads to a decrease in the average distance between a market and a distribution center, which falls by roughly 125mi for Dollar General and slightly smaller amounts for the other two chains.¹² The locations of these in 2019 are shown in [Figure A6](#).

We use demographic information from the Census and the Circana Consumer Network

¹⁰We note that the “Grocery” retail channel in the Circana data includes both grocery stores and supermarkets. In this paper, when studying the impact on market structure, we distinguish between independent grocery stores and supermarket chains.

¹¹Studies have compared household scanner data with data from other sources (e.g., Consumer Expenditure Survey, FoodAPS, and supermarket chains’ own databases) to assess differences in reporting, see for instance [Einav et al. \(2010\)](#) for Nielsen Homescan and [Sweitzer et al. \(2017\)](#) for Circana Consumer Network. These studies find discrepancies in reported prices and consistently lower expenditures in the household scanner datasets, especially for un-packaged and random weight products. Therefore, our measures of annual spending likely underestimate the true value. To alleviate this problem, we perform robustness checks in our reduced form analysis by imposing a minimum number of weeks a household reports spending.

¹²We provide details about the market definition used in [Section 5.1](#).

Figure 1: Store counts by firm type

to document consumer heterogeneity across locations with varying dollar store densities. Table 2 shows summary statistics of census demographic information for the locations entered by dollar store chains prior to 2010, during the 2010-2019 period, and locations never entered. A location is defined at the Census Tract level. Dollar store entry occurs in locations that have significantly lower incomes per capita and rents than other locations, and a significantly higher share of the population that is black or below the poverty line. Entered locations are also significantly closer to distribution centers than non-entered locations.¹³

Finally, we characterize the household types that display a revealed preference for the dollar store format. First, we compare the demographics of households with a large spending share at the dollar store channel (top 95th percentile and above) post-dollar store entry to households with no spending at the dollar store channel post-entry. This comparison is only among households in locations with dollar store entries and is shown in Table 3. Comparing columns 1 and 2 shows that these two groups differ on several dimensions: households with high dollar store spending shares are significantly more likely to be low income, with a female household head, from a minority group, unmarried, unemployed, and without access to a vehicle. The latter group also spends less on fresh produce and at the grocery retail channel.

¹³The patterns that emerge using the Census or ACS data are consistent with household demographics in the Circana Consumer Network panel. Table A3 in Appendix E shows that households experiencing many dollar stores entries have lower (household) income, are more likely to have a female household head, without children, and are less likely to be white, married, employed, with access to a vehicle.

Table 2: Market Summary Statistics

	(1) Pre-2010 Entry Only	(2) 2010-2019 Entry	(3) Never Entered
N	9778	12872	50378
Mean Population	4689.9 (2193.5)	4962.8 (2566.1)	4263.9 (2295.8)
Mean Income	22686.3 (7520.7)	23538.8 (8178.7)	31315.2 (16696.5)
Mean Residential Rents	753.9 (252.6)	785.9 (275.4)	1064.8 (455.8)
Mean Share White	.738 (.24)	.739 (.253)	.713 (.254)
Mean Share Black	.166 (.225)	.162 (.234)	.127 (.210)
Mean Share in Poverty	.176 (.108)	.165 (.106)	.136 (.118)
Share HH w/ Vehicle Access	.911 (.084)	.917 (.091)	.904 (.135)
Mean Distance to DG DC	157.8 (134.1)	171.8 (142.5)	227.9 (292.9)
Mean Distance to DT DC	188.2 (111.2)	191.4 (119.7)	189.5 (239.8)
Mean Distance to FD DC	190.1 (124.2)	207.2 (126.1)	275.2 (296.3)

Notes: Unit of observation is the Census Tract. Means are computed using 2019 data. Standard deviation across tracts appears in parentheses below each row.

Second, to isolate preferences that are not merely due to dollar store proximity, we identify households with high dollar store spending who have no dollar stores within 2 miles. All else equal, these households are willing to travel longer distances to shop at this store format and may, therefore, benefit from entry as it reduces their travel costs. To implement this comparison, we select the sample of households with no dollar stores within 2 miles and regress their dollar store spending per year on household demographics (age, income, education, race, household size, marital status, occupation, and weekly hours worked), their retail environment (number of stores by format within 2 miles and from 2 to 5 miles of the household), and the survey year. Controlling for the retail environment is important because low-income households with no dollar stores within 2 miles may also lack access to other retailers (grocery and supermarkets).

We find that the main dimensions of heterogeneity are race and household income. Figure 2 shows the estimated coefficients for income and race. Low income households and black households have significantly higher spending at dollar stores, even when such stores are located far from the household.

Table 3: Demographics of Circana panelists experiencing at least one dollar store entry over the sample period

Variable	By DS Spending Share Post-DS Entry		
	No Spending	High Spending (Top 5%)	Δ (t-stat)
Income (000s)	75.08 (45.68)	41.02 (32.38)	96.6
Low-Income (<35k)	0.21 (0.41)	0.55 (0.50)	-69.6
High-Income (>100k)	0.22 (0.42)	0.04 (0.20)	71.7
Years education	15.13 (2.18)	13.91 (2.08)	57.5
No female head	0.17 (0.38)	0.14 (0.34)	9.6
No male head	0.24 (0.42)	0.42 (0.49)	-36.9
With children	0.17 (0.37)	0.12 (0.33)	13.8
Age	57.00 (13.10)	59.47 (11.41)	-20.8

Employed	0.57 (0.50)	0.41 (0.49)	32.3
No vehicle	0.04 (0.20)	0.10 (0.30)	-8.5
Pre-Entry Fresh Produce Spending	142.10 (140.42)	66.64 (69.54)	88.2
Pre-Entry GS Channel Spending	1929.54 (1434.27)	1186.75 (965.85)	69.6
Pre-Entry DS Channel Spending	2.20 (24.76)	223.87 (267.30)	-88.7
Observations	63,535	11,452	

Note: The unit of observation is the household-year, for the subsample of households who experience at least one dollar store entry within 2 miles over the sample period. The table shows mean values and standard errors are in parenthesis. Columns (High Spending) shows households with a share of spending at the dollar channel in the 95th percentile or above (9% of total spending). For households with two household heads, we use the mean of age, employment hours, educational attainment for male and female household heads. Household Income is available in 12 bins. Mean income is computed by taking the mid-range of each bin. The top bin (>\$100k) is coded as \$150,000.

3 Reduced Form Analysis

3.1 Effects on Market Structure

In this section, we present evidence on the impact of dollar store chain entry on local retail markets. Our goal is to evaluate whether or not dollar store chain entry leads to decreases in the number of local independent retailers and grocery stores. We use our data containing the annual universe of retailers and study the period of rapid expansion of dollar store chains between 2010 and 2019.

During this time period, we observe 14,554 dollar store chain entries. To study the local effects of these entries, we break markets into locations defined as Census tracts. For each location, we obtain its population-weighted centroid and define distance bands around each location using radii of 0-2mi, 2-5mi, and 5-10mi (see [Ellickson and Grieco \(2013\)](#) for a similar approach). Our main outcome of interest is the number of independent grocery stores.

Our identification strategy for measuring the effects of dollar store chain entry on these outcomes is to use tract-level fixed effects to account for time-invariant unobserved market

Figure 2: These figures show the estimated coefficients on income and race in the regression of dollar store spending on household demographics and their retail environment. Results are for the subsample of households with no dollar stores within 2 miles. Year fixed effects are included. For household income, the first bin corresponds to income less than \$10,000, bin 7 corresponds to income in the range \$35,000 to \$45,000, bin 10 to income in the range \$60,000 to \$70,000, the highest bin corresponds to income greater than \$100,000 per year. Standard errors are clustered at the household level.

characteristics and county-year fixed effects to account for time-varying trends at the market level. We also incorporate time-varying demographic variables at the census tract level. These are intended to control for local trends in population or income associated with economic shocks. We include population, median income, and level of residential rents as well as the annual growth rate in each of these variables. We also include a time-varying measure of overall business activity by constructing the total number of active businesses (excluding grocery and dollar stores) at the tract-year level, which we label “business density”. We include both the level and annual growth rate in business density as additional controls.

We estimate effects using the following specification:

$$Y_{lbt} = \delta DS_{lt} + \beta \mathbf{X}_{lbt} + \lambda_l + \alpha_{mt} + \epsilon_{lbt} \quad (1)$$

where λ_l and α_{mt} represent location and county-time fixed effects, and the objects of interest δ are the coefficients on the number of dollar store chain entry events in location l in period t . The outcome variable Y_{lbt} is the number of independent grocery stores at distance band b around the entry location l in period t . We also define \mathbf{X}_{lbt} , the local demographics (including growth rates), at this level. To capture potential non-linear effects of changes in market structure, we include DS_{lt} as a categorical variable.

In Table 4 we show results for different specifications of controls and fixed effects where

the outcome variable is the number of independent grocery stores in location l . We find that, once location FE or demographic controls are included, there is a consistent negative effect on the number of independent local grocery stores that is increasing in the number of dollar store entries. This effect is small for a single dollar store entry, but increases to $-.32$ for two entries, and a decrease of more than 1 grocery stores in locations with 3+ entries.

Table 4: Effects of DS Entry (0-2mi) on Number of Grocery Stores

	(1)	(2)	(3)	(4)	(5)
	All Markets	All Markets	All Markets	All Markets	All Markets

Adjusted R^2	0.072	0.59	0.98	0.98	0.98
Mean Pre-Entry	2.71	2.71	2.71	2.71	2.71

Notes: Unit of observation is the location-year. Standard errors (in parenthesis) clustered at the location level. Controls for time-varying local demographics (income, population, residential rents, and the one-year percent change in each) and business density are included.

Table 5 shows how these effects vary by the distance from the entry location. We study regions defined by radii of 0-2mi, 2-5mi, and 5-10mi from the entry location.¹⁴ The results show a substantial fall in the number of grocery stores in the 2-mile radius around where the dollar store entry occurs. In the area 2-5 miles from the dollar store entry there is a smaller but still significant effect when there are more than one entrants, and in the area 5-10 miles away there are no detectable negative effects of dollar store entry.

Three conclusions follow from these results. First, the negative effect of dollar store entry on grocery stores that we find is not spuriously driven by larger market-level or regional economic shocks. Second, shopping patterns for dollar stores and independent grocery stores seem to take place primarily over fairly small distances. And third, in the local area in which

¹⁴Each demographic variable is calculated for the region where effects are being measured.

a dollar store entry takes place the effects on grocery stores is increasing in the number of dollar stores that enter.

Table 5: Effect of DS Entry (by distance band) on Number of Grocery Stores

Market*Year FE	Yes	Yes	Yes
Observations	453,657	307,321	263,488
F-stat	89.6	29.9	14.2
Adjusted R^2	0.98	0.99	0.99
Mean Pre-Entry	2.72	3.97	6.28

Notes: Unit of observation is the location-year. Standard errors (in parenthesis) clustered at the location level. Time and location fixed effects are included. Controls for time-varying local demographics (income, population, residential rents, and the one-year percent change in each) and business density are included, each is calculated for the radius area corresponding to the dependent variable.

Next, we perform an event study analysis to visualize these results over the years before and after the dollar store chain entry occurs. In this specification, we estimate:

$$Y_{lbt} = \sum_{\tau} \delta_{\tau} E_{l,t-\tau} + \beta \mathbf{X}_{lbt} + \lambda_l + \alpha_{mt} + \epsilon_{lbt} \quad (2)$$

where E_{lt} denote a dummy for whether a dollar store entry has occurred in location l by period t . This differs from the specification in equation (1) in that now the coefficients on dollar store entry are subscripted by τ , the difference in years measured relative to the entry date. This allows for both dynamic policy effects, such as a delay in the effect on local markets as the dollar store's sales ramp up, and for detecting the presence of pre-trends in grocery store activity prior to dollar store entry. For this analysis, we also focus only on a binary dummy for whether or not an entry occurs, rather than the number of entries as used above. The omitted category is $\tau = -1$ so that all cumulative effects are relative to

the period before entry.

This design is essentially a Difference-in-Difference with two-way fixed effects (TWFE) and a staggered roll-out of treatment. This type of empirical design has been shown to have the potential for biased results (Goodman-Bacon (2021), Sun and Abraham (2021)). Consequently, we present results based on heterogeneity-robust estimators, e.g., Callaway and Sant’Anna (2021).¹⁵ We plot the results in Figure 3 in the manner suggested by Freyaldenhoven et al. (2021), with confidence intervals adjusted for multiple hypothesis testing. The left panel shows the effects of dollar store entry on the number of grocery stores in the 0-2mi radius and the right panel shows effects in the 2-5mi radius. In both panels, we detect no pre-trend in the number of grocery stores, followed by a clear downward trend after the time of dollar store entry. Several years after the initial dollar store entry, the effect on the number of grocery stores grows quite large.

Figure 3: The effects of dollar store entry on local independent grocery stores measured in the 0-2 mile radius around entry (left panel) and in the 2-5 mile radius around entry (right panel). Results are from an event study analysis using a heterogeneity-robust estimator proposed by Callaway and Sant’Anna (2021). Confidence bands show the uniform sup-t confidence intervals adjusted for multiple hypothesis testing.

3.2 Effects on Consumers’ Shopping Behavior

This section studies how dollar store entry and grocery store exit affects households’ shopping behavior. We exploit variation in local supply within household in an event study framework, as in Allcott et al. (2019). We begin by analyzing how the changes in market structure

¹⁵In Figure A2 of Appendix E, we present results from the TWFE implementation as well as several other heterogeneity-robust estimators based on imputation (Borusyak et al. (2021)) and manual aggregation (Sun and Abraham (2021)) that have been suggested in the literature and they provide consistent results.

highlighted in the previous section affect aggregate food spending. Next, we show that the adverse impact of dollar store entry on the number of grocery stores is reflected in spending and trip diversion from the grocery to the dollar store retail channel. Finally, we examine how the above market structure changes translate into spending on various food categories and the nutritional value of households’ shopping baskets. We aim attention at spending and volume of purchases of fresh produce, specifically, because access to this particular food group has been at the center of the dollar store policy debate.

In this section, the unit of analysis is the household–year. We again consider both static and dynamic (event study design) specifications. Let DS_{bct} denote the number of dollar store entries that have occurred within distance band b (e.g., 0-2mi, 2-5mi) from census tract c by period t . Let \mathbf{X}_{it} denote time-varying household characteristics (e.g., age, education, employment, marital status). Let Y_{ict} denote the outcome variable for household i living in census tract c in period t . We consider the following static specification

$$Y_{ict} = \delta DS_{bct} + \beta \mathbf{X}_{it} + \gamma_i + \eta_t + \epsilon_{ict} \quad (3)$$

where γ_i and η_t are household and time fixed effects.

As the effects we estimate are likely persistent and heterogeneous over time, we also consider a dynamic specification in an event study framework. Let E_{bct} denote a dummy for whether a dollar store entry has occurred within distance band b (e.g., 0-2mi, 2-5mi) from census tract c by period t . We consider the following dynamic specification

$$Y_{ict} = \sum_{\tau} \delta_{\tau} E_{bc,t-\tau} + \beta \mathbf{X}_{it} + \gamma_i + \eta_t + \epsilon_{ict} \quad (4)$$

Spending and number of trips by retail channel.

Table 6 shows the effect of dollar store entry (within 2 miles of the household) on spending and the number of yearly trips by retail channel.¹⁶ The results indicate that dollar stores divert spending away primarily from the grocery and convenience retail channels, but not from supercenters or club stores. Entry is associated with an increased number of trips to the dollar channel, from 4.8 to 5.5 trips following one entry and 5.8 following two entries. The impact of entry on the number of grocery and convenience trips is negative and significant.

Spending on fresh produce and dollar store entry.

Next, we turn to the effect on fresh produce spending, a key outcome of interest for policy-makers. Table 7 shows the effect of dollar store entry within 2mi and from 2 to 5mi of the

¹⁶Retail channels, as defined by Circana, correspond to broad retail categories. The “Grocery” channel includes both supermarkets and grocery stores but excludes supercenters and club stores. Other smaller retail categories (in terms of spending share), not shown in Table 6, include farmers’ markets, military commissaries, and bulk food stores which also see sales diversion to dollar stores.

Table 6: Effect of DS Entry (0-2mi) on Spending and Number of Trips by Retail Channel

Mean Pre-Entry	2917.3	1768.3	32.3	777.2	14.6	57.8	4.85	22.4	2.16

Notes: Unit of observation is the household-year. Standard errors (in parenthesis) clustered at the household level. Year and household fixed effects are included. Controls for time-varying household demographics (income, education, age, household size, marital status, occupation, weekly hours worked) are included. Results are shown for all panelists in the sample. The first column shows aggregate spending. SC/Club stands for the Supercenter and Club store channel. Conv stands for the convenience store channel.

household on fresh produce spending. Overall, we find a negative and significant effect of entry within 2mi of the household on produce spending across samples. The magnitude of the effect increases with the number of dollar store entries but is overall modest in size.

We investigate the heterogeneity in this effect by household characteristics. Figure 4 shows the coefficients on dollar store entry for the balanced panel (column (2) of Table 7) interacted with household income (in 12 bins, top panel) and vehicle access (bottom panel). The results indicate that the negative effect of dollar store entry on fresh produce spending is mainly driven by lower-income households (income up to \$45,000 or bins 1 to 7). For this group, a single dollar store entry reduces spending by 2.3% to 13.8%, two entries reduce spending by 5.1% to 25.8%, and three or more entries reduce spending by 7.24% to 30.44% depending on the household income bin. Moreover, households without vehicle access (a proxy for travel costs) experience a significantly larger decline in their fresh produce spending following one and two entries, although this group is small.

To put these effects into a broader perspective, we compute the difference in fresh produce spending between low and high-income households, controlling for household size, age, and year indicators. We compare households with annual income below \$45,000 to households with annual income greater than \$70,000. We find that the reduction in fresh produce spending due to dollar store entry explains between 13.2% and 27% of the difference in fresh produce spending across high and low income households.

Table 7 shows that these effects are localized spatially. Entry of dollar stores in the 2-5mi distance band (columns (4) to (6)) does not significantly affect produce spending.

Table 7: Effect of DS Entry (by distance band) on Fresh Produce Spending

Spending Pre-Entry	130.9	146.4	155.4	126.1	137.9	144.6

Notes: Unit of observation is the household-year. Standard errors (in parenthesis) clustered at the household level. Year and household fixed effects are included. Controls for time-varying household demographics (income, education, age, household size, marital status, occupation, weekly hours worked) are included. The balanced panel (“Bal”) corresponds to households observed for at least 9 consecutive years. The “RW” panel reports complete purchases of random weight products.

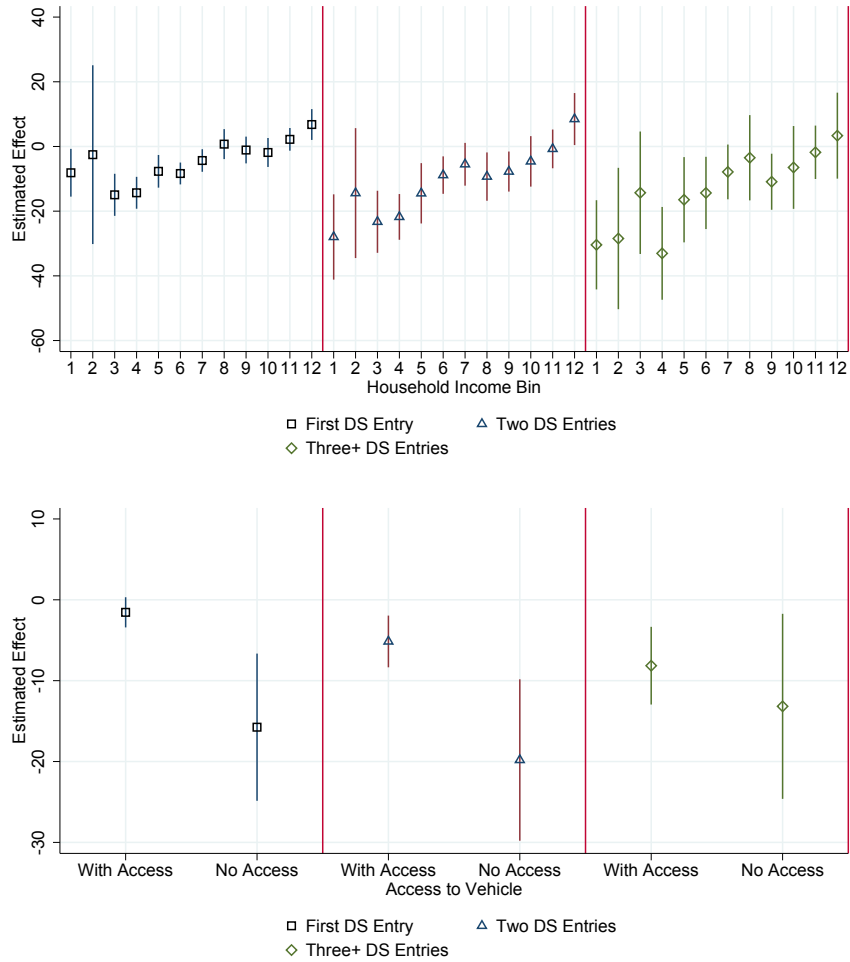

Figure 4: The effect of dollar store entry at the 0-2mi band around the household on fresh produce spending, by household income bin (top panel) and access to vehicle (bottom panel). Results are shown for the balanced panel. For household income, the first bin corresponds to income less than \$10,000, bin 7 corresponds to income in the range \$35,000 to \$45,000, bin 10 to income in the range \$60,000 to \$70,000, the highest bin corresponds to income greater than \$100,000 per year. Standard errors are clustered at the household level.

Figure 5 shows the corresponding event study plots for the balanced sample, using a two-way fixed effect as well as a heterogeneity-robust estimator (Callaway and Sant’Anna (2021)).¹⁷ Consistent with the static analysis, we find that the effects are localized and negative only at the 0-2mi range. Moreover, the negative impact on fresh produce spending is dynamic, with the magnitude increasing in the time since entry.

Figure 5: The effects of dollar store entry at the 0-2mi (left panel) and 2-5mi (right panel) bands around the household on spending on fresh produce. Results are from an event study analysis on the balanced panel, using a TWFE and a heterogeneity-robust estimator proposed by Callaway and Sant’Anna (2021). Household and year fixed effects are included. Confidence bands show the uniform sup-t confidence intervals adjusted for multiple hypothesis testing.

As a robustness check, we also perform the event study analysis on subsamples of households controlling for the number of weeks a household reports spending (see footnote 11 for a discussion of known under-reporting issues in the Nielsen and Circana household scanner data). The results, shown in Figure A4 in Appendix E, are quantitatively similar.

Spending on fresh produce and grocery store exit.

The reduction in fresh produce spending documented above may be due to a direct effect (e.g., substitution away from produce due to preferences for the dollar store format and products) and an indirect effect (e.g., reduced access to produce from changes in market structure). We provide evidence that the impact of dollar store entry on fresh produce spending acts in part through exits of grocery stores and reduced access. Table 8 shows the effect of dollar store entry on fresh produce spending, controlling for the number of grocery store exits (all in the 0-2mi radius). Given the effect heterogeneity uncovered in Figure 4,

¹⁷We experiment with several other heterogeneity-robust estimators based on imputation (Borusyak et al. (2021)) and manual aggregation (Sun and Abraham (2021)). Results are shown in Figure A3 of Appendix E.

we interact these market structure changes with household income (below or above bin 7).

Comparing column (1), which includes dollar store entries only, to column (2) indicates that, for low-income households, grocery store exits explain a significant proportion (43%) of the effect of dollar store entry on fresh produce spending. For instance, the aggregate effect of three dollar store entries on low-income households' spending (-\$15.86 in column (1)) can be decomposed into a direct effect (-\$8.17 in column (2)) and an indirect effect from one grocery store exit (-\$6.82 in column (2)).¹⁸

Spending on other food categories.

One argument in favor of dollar store entry is its potential for lowering prices and increasing cost savings for consumers. We therefore test whether dollar store entry reduces total expenditure on other food categories. [Table 9](#) show spending on food categories ranging from Soda and Snacks to Meals (soup, rice, and pasta). The majority of changes in spending are insignificant, except for frozen produce, on which spending increases following three or more entries. We note, however, that the latter effect is not robust when broken down by income.¹⁹

Quantities of fresh produce purchased.

Finally, we investigate whether these changes in fresh produce spending translate into meaningful changes in volumes consumed. While lower expenditures might reflect a reduction in consumption, it might also reflect the fact that consumers potentially face lower prices, if for instance, grocery stores respond to entry by lowering fresh produce prices. We isolate the effect on quantities purchased by computing volumes of fresh produce purchased. [Figure 6](#) shows an event study plot of the effect of dollar store entry on the volume of fresh produce purchased in ounces. The results indicate that entry within 2mi of the household leads to a significant reduction in volumes of fresh produce purchased of approximately 5%. For completeness, we include the corresponding static analysis in [Table A4](#) of [Appendix E](#).

On the whole, the findings in [sections 3.1](#) and [3.2](#) point to a large impact of dollar store expansion on market structure and a modest but significant impact on consumers' dietary choices. The latter average effect masks important heterogeneity across consumers: low-income households (annual income below \$45,000) and households with high travel costs experience large declines in fresh produce spending whereas higher-income households are not affected. While previous research (e.g., [Allcott et al. \(2019\)](#)) has shown that entry of

¹⁸Section [3.1](#) shows that three dollar stores entries displace on average one grocery store. We also run alternative specifications for [Table 8](#) (e.g., including only grocery store exits but not dollar store entries) and consistently find that grocery store exits lead to a reduction in fresh produce spending for low-income households.

¹⁹Frozen produce spending increases following three or more entries only for households in income bins 4 and 5 (\$15,000 to \$25,000 per year). The effect does not display the monotonicity found for fresh produce spending and displayed in [Figure 4](#).

Table 8: Decomposition of the Effect of DS Entry (0-2mi) on Fresh Produce Spending

	Dependent Variable: Spending on Fresh Produce

Notes: Unit of observation is the household-year. Standard errors (in parenthesis) clustered at the household level. Year and household fixed effects are included. Controls for time-varying household demographics (income, education, age, household size, marital status, occupation, weekly hours worked) are included. Results are shown for the balanced panel. Each column corresponds to a product category: (1) is canned produce, (2) is frozen produce, (3) is soda, snacks, candy and crackers, (4) is meals (incl. rice, pasta, soup), (5) is dairy, (6) is refrigerated and frozen meats, (7) is refrigerated and frozen baked goods, desserts, dough, and beverages.

Figure 6: The effects of dollar store entry at the 0-2mi (left panel) and 2-5mi (right panel) bands on fresh produce volume purchased. Results are from an event study analysis on the balanced panel, using a TWFE and a heterogeneity-robust estimator proposed by [Callaway and Sant’Anna \(2021\)](#). Household and year fixed effects are included. Confidence bands show the uniform sup-t confidence intervals adjusted for multiple hypothesis testing.

grocery stores and supermarkets has economically small effects on healthy grocery shopping, the analysis above demonstrates that (1) grocery stores are driven out by dollar store entry in close proximity; (2) the exit of many grocery stores is associated with a moderate but significant reduction in spending on and volumes of fresh produce. This asymmetric impact of grocery store entries and exits on healthy grocery shopping may be tied to consumer inertia in store and brand choices ([Ho et al. \(1998\)](#), [Dubé et al. \(2010\)](#)). Inertia in households’ shopping may create asymmetries in the response to positive or negative shocks to their retail environment.

4 Industry Model

In this section, we describe a structural model of the evolution of the retail industry and the entry and exit game played by rival retailers over time. This model serves three purposes. First, when we take this model to the data, we can recover parameters informative on why the dollar store format has been so successful at expanding and why dollar stores cause nearby grocery stores to exit. Second, as we found previously that the effects of dollar store entry on local market structure are nonlinear and highly spatial, we incorporate these features into the model to evaluate the net impact of dollar store expansion on retail markets. Finally, we can use the model to evaluate counterfactual outcomes if policies such as proposed dollar store bans were widely implemented.

Next, we describe the basic structure of the model, as well as the equilibrium concept.

In the next section, we describe the empirical implementation and results.

Players Each market contains two types of potential entrants: multi-store firms (i.e., chains) and a set of independent single-store firms. Markets are assumed to be completely independent of each other. We index firms by $i = 1, \dots, I_m$, and assume that market m has $I_{s,m}$ single-store firms, the remaining $I_{c,m} = I_m - I_{s,m}$ firms being chains (abusing notation, we also use $I_{s,m}$ and $I_{c,m}$ to denote sets of firms). Time is discrete and denoted by $t = 1, \dots, \infty$.

In what follows, we consider a market m that is partitioned into locations $l = 1, \dots, L$.

State space At the beginning of period t a chain's network of stores is represented by the vector $\mathbf{n}_{it} = (n_{i1t}, \dots, n_{iLt})$, where n_{ilt} is the number of stores that firm i operates in location l at period t . For simplicity, we assume that a chain can have up to \bar{n} stores in a location, such that $n_{ilt} \in \{0, 1, \dots, \bar{n}\}$. Single-store firms can operate only one store per market. The spatial market structure at period t is represented by the vector $\mathbf{n}_t = (\mathbf{n}_{it})_{i \in I}$. Let \mathbf{n}_{-it} denote the network of stores of all firms other than i .

There are market and location characteristics that evolve exogenously over time, denoted $\mathbf{x}_{mt} = \{x_{mlt}\}_{l \in L}$. These include the population, income per capita, and rents in each location. Market-level characteristics include the number of other store types (e.g., drug stores, supermarkets, and gas stations) which are not players in the game but can be payoff-relevant.²⁰ For multi-store firms, let d_{imt} denote market m 's distance from i 's closest distribution center and $\mathbf{d}_{mt} = (d_{imt})_{i \in I_c}$ the vector collecting this variable for all chains. This vector evolves deterministically over time, as the chains expand their network of distribution centers. The transition matrices for these variables are denoted: $f(x_{ml,t+1}|x_{ml,t})$ and $h_t(d_{im,t+1}|d_{imt})$. The latter transition matrix is deterministic.²¹

Every period, the vector of public information variables includes the spatial market structure \mathbf{n}_t and market and location level characteristics. All these variables are publicly observed and collected, from the perspective of firm i , into the vector $\mathcal{M}_{j,i,t}$, with particular realization j at time t . That is

$$\mathcal{M}_{j,i,t} = (\mathbf{n}_{it}, \mathbf{n}_{-it}, \mathbf{x}_{mt}, \mathbf{d}_{mt}) \quad (5)$$

Actions

Multi-store firms We assume that a chain may open or close at most one store per period.²²

²⁰This helps capture, for instance, dollar store chains' tendency to locate away or near big-box stores such as Walmart.

²¹We assume that players have perfect foresight over the evolution of distribution networks during the sample period. While endogenizing distribution centers' openings would be an interesting addition to the model, this is complicated in practice because of the small number of distribution centers which prevents the precise estimation of these choice probabilities.

²²There are only two observations out of 25,380 (chain-market-period) where a chain closes two stores simultaneously and 26 observations where a chain opens two stores or more simultaneously. We exclude

Let a_{it} be the decision of firm i at period t such that: $a_{it} = l_+$ represents the decision to open a new store at location l ; $a_{it} = l_-$ means that a store at location l is closed; and $a_{it} = 0$ the firm chooses to do nothing. The set of feasible choices for firm i at period t , denoted $A(\mathbf{n}_{it})$, is such that $A(\mathbf{n}_{it}) = \{0\} \cup \{l_+ : n_{ilt} < \bar{n}\} \cup \{l_- : n_{ilt} > 0\}$. Note that this choice set can have more than $L + 1$ choice alternatives (if, for some l , $0 < n_{ilt} < \bar{n}$). Multi-store firms are *long-lived*, that is, they can delay entry into the market. This feature allows us to capture delays in entry because a chain expects to open a distribution center closer to the market in a future period. Exit from a market (that is, $\mathbf{n}_{it} = \mathbf{0}_L$ given that firm i was operating a store in $t - 1$) is a terminal action.²³

Single-store firms A single-store firm can enter if it is a potential entrant: $A(\mathbf{n}_{it}) = \{0\} \cup \{l_+\}$; or it can exit if it is an incumbent: $A(\mathbf{n}_{it}) = \{0\} \cup \{l_- : n_{ilt} = 1\}$. Firms that exit or potential entrants that decide to stay out are replaced by a new set of potential entrants in the following period.

Firms' choices are dynamic because of partial irreversibility in the decision to open a new store, i.e., sunk costs. At the end of period t firms simultaneously choose their network of stores \mathbf{n}_{t+1} with an understanding that they will affect their variable profits at future periods. We model the choice of store location as a game of incomplete information, so that each firm i has to form beliefs about other firms' choices of networks. More specifically, there are components of the entry costs and profits of a store which are firm-specific and private information.

Flow profits (and components) Firm i 's current profits, net of private information shocks, are

$$\pi_{it}(a_{it}, \mathcal{M}_{j,i,t}) = VP_i(\mathcal{M}_{j,i,t}) - FC_{it}(\mathcal{M}_{j,i,t}) - EC_{it}(a_{it}) + EV_{it}(a_{it}), \quad (6)$$

where $VP_i(\mathcal{M}_{j,i,t})$ are variable profits, FC_{it} is the fixed cost of operating all the stores of firm i , EC_{it} is the entry or set-up cost of a new store, and EV_{it} is the exit value of closing a store.

Variable profits $VP_i(\mathcal{M}_{j,i,t})$ are obtained as the sum of profits over all stores firm i is operating in the market at time t , that is

$$VP_i(\mathcal{M}_{j,i,t}) = \sum_{l=1}^L n_{ilt} vp_{i,l}(\mathcal{M}_{j,i,t}) \quad (7)$$

these observations in the estimation procedure described in Section 5.3.2.

²³Exit by chains from a market is observed to be permanent in the sample and time period we consider. This assumption implies that in the long-run, the probability that "all chains have existed from the market" converges to one. In practice, given annual exit rates of the order of 2% for chains, this would not be expected to occur for many decades.

where $vp_{i,l}(\mathcal{M}_{j,i,m,t})$ are per-store profits. For a store in location l , variable profits are a function of the exogenous characteristics and the number of (own and rival) stores in location l and surrounding locations. Following Seim (2006), we capture this dependence by defining these variables for various distance bands, $b = 1, \dots, B$, around location l

$$vp_{i,l}(\mathcal{M}_{j,i,t}) = \sum_{b=1}^B \alpha_i^b x_{mlt}^b + \sum_{b=1}^B \beta_{io}^b n_{ilt}^b + \sum_{b=1}^B \sum_{f=1}^F \beta_{if}^b n_{flt}^b \quad (8)$$

where f denotes the type of competitors (i.e., dollar store, grocery or combination store, convenience store), and b are distance bands around location l (e.g., 0-2 miles, 2-5 miles). The variables x_{mlt}^b , n_{ilt}^b , and n_{flt}^b correspond to exogenous location characteristics, own stores, and rival stores of type f in distance band b around location l . The second term captures cannibalization and/or economies of density, the third term captures business stealing between rival stores.

For chains, fixed operating costs depend on the distance to the closest distribution center and capital costs (proxied by residential rents). If a chain is operating at least one store in the market, fixed costs are

$$FC_{it}(\mathcal{M}_{j,i,t}) = \theta_{1,c}^{FC} d_{imt} + \sum_{l=1}^L \theta_{2,c}^{FC} rent_{mlt} \quad (9)$$

For single-store firms, fixed costs depend only on capital costs: $FC_{it} = \theta_s^{FC} rent_{mlt}$.

The specification of entry costs is

$$EC_{it} = \sum_{l=1}^L 1\{a_{it} = l_+\} \theta_i^{EC}. \quad (10)$$

In estimation, we will restrict entry costs to depend only on the type of the firm f but not the identity of firm i .

The exit value is specified as:

$$EV_{it} = \sum_{l=1}^L 1\{a_{it} = l_-\} \theta_i^{EV}. \quad (11)$$

Similarly to entry costs, the exit value θ_f^{EV} depends only on the type of the firm f .

At the beginning of period t , each firm draws a vector of private information shocks associated with each possible action $\epsilon_{it} = \{\epsilon_{it}(a)\}_{a \in A(\mathbf{n}_{it})}$. We assume that the shocks ϵ_{it} are independently distributed across firms and over time and have a cumulative distribution function $G(\cdot)$ that is strictly increasing and continuously differentiable with respect to the

Lebesgue measure. These two assumptions allow for a broad range of specifications for the ϵ_{it} , including spatially correlated shocks. In our application, these shocks will be distributed Type 1 extreme value, scaled by a parameter θ^ϵ .²⁴

It will be convenient to distinguish two additive components in the current profit function:

$$\Pi_{it}(a_{it}, \mathcal{M}_{j,i,t}, \epsilon_{it}) = \pi_i(a_{it}, \mathcal{M}_{j,i,t}) + \epsilon_{it}(a_{it}). \quad (12)$$

Value function and Equilibrium concept We focus on Markov-Perfect Bayesian Nash Equilibria (MPE). We first define firm strategies, value functions, and then the equilibrium conditions.

A firm's strategy, at time t , depends only on its payoff relevant state variables $(\mathcal{M}_{j,i,t}, \epsilon_{it})$. A strategy profile is denoted

$$\alpha = \{\alpha_{i,t}(\mathcal{M}_{j,i,t}, \epsilon_{it})\}_{i \in I, t \geq 0}.$$

Given strategy profile α , firm i 's value function satisfies

$$V_{i,t}^\alpha(\mathcal{M}_{j,i,t}, \epsilon_{it}) = \max_{a_{it} \in A(n_{it})} \{v_{i,t}^\alpha(a_{it}, \mathcal{M}_{j,i,t}) + \epsilon_{it}(a_{it})\} \quad (13)$$

where $v_{i,t}^\alpha(a_{it}, \mathcal{M}_{j,i,t})$ are choice-specific value functions, defined as

$$\begin{aligned} v_{i,t}^\alpha(a_{it}, \mathcal{M}_{j,i,t}) &= \pi_i(a_{it}, \mathcal{M}_{j,i,t}) \\ &+ \beta \int V_{i,t+1}^\alpha(\mathcal{M}_{j,i,t+1}, \epsilon_{i,t+1}) dG(\epsilon_{i,t+1}) dF_t(\mathcal{M}_{j,i,t+1} | a_{it}, \mathcal{M}_{j,i,t}) \end{aligned} \quad (14)$$

where the next-period state $\mathcal{M}_{j,i,t+1}$ is formed of the next-period spatial market structure \mathbf{n}_{t+1} , and market and firm-level covariates $(\mathbf{x}_{m,t+1}, \mathbf{d}_{m,t+1})$. The distribution over next-period states is given by the transition probabilities $f(\mathbf{x}_{m,t+1} | \mathbf{x}_{m,t})$ and $h_t(\mathbf{d}_{m,t+1} | \mathbf{d}_{m,t})$ of exogenous states, and the distribution of rivals' shocks $\prod_{j \neq i} g(\epsilon_{j,t})$ and strategies α_j for $j \neq i$.

A MPE is a strategy profile α^* such that for every player, state, and period

$$\alpha_{i,t}^*(\mathcal{M}_{j,i,t}, \epsilon_{it}) = \arg \max_{a_{it} \in A(n_{it})} \{v_{i,t}^{\alpha^*}(a_{it}, \mathcal{M}_{j,i,t}) + \epsilon_{it}(a_{it})\} \quad (15)$$

The probability that firm i chooses action a_{it} in period t given state $\mathcal{M}_{j,i,t}$ (hereafter, the conditional choice probability or CCP) is defined as

²⁴These shocks can be thought of as representing the firms' idiosyncratic conditions in terms of real estate information, corporate finance, and other managerial or organizational climate for store-development activities (Igami and Yang (2016)).

$$P_t^\alpha(a_{it}|\mathcal{M}_{j,i,t}) = \Pr(\alpha_{i,t}(\mathcal{M}_{j,i,t}, \epsilon_{it}) = a_{it}|\mathcal{M}_{j,i,t}) \quad (16)$$

We find it convenient to express the choice-specific value function as a function of CCPs instead of strategies. That is,

$$v_{i,t}^{\mathbf{P}}(a_{it}, \mathcal{M}_{j,i,t}) = \pi_i(a_{it}, \mathcal{M}_{j,i,t}) + \beta \sum_{a_{-it}} \int \bar{V}_{i,t+1}^{\mathbf{P}}(\mathcal{M}_{j,i,t+1}) dF_t(\mathcal{M}_{j,i,t+1}|\mathcal{M}_{j,i,t}, a_t) P_{-i,t}(a_{-it}|\mathcal{M}_{j,i,t}) \quad (17)$$

where $a_t = (a_{it}, a_{-it})$ and $\bar{V}_{i,t}^{\mathbf{P}}$ is the *ex-ante* value function expressed before the realization of the private shock ϵ_{it}

$$\begin{aligned} \bar{V}_{i,t}^{\mathbf{P}}(\mathcal{M}_{j,i,t}) = & \int \max_{a_{it} \in A(n_{it})} \left\{ \pi_i(a_{it}, \mathcal{M}_{j,i,t}) + \epsilon_{it}(a_{it}) \right. \\ & \left. + \beta \sum_{a_{-it}} \int \bar{V}_{i,t+1}^{\mathbf{P}}(\mathcal{M}_{j,i,t+1}) dF_t(\mathcal{M}_{j,i,t+1}|\mathcal{M}_{j,i,t}, a_t) P_{-i,t}(a_{-it}|\mathcal{M}_{j,i,t}) \right\} dG(\epsilon_{it}). \end{aligned} \quad (18)$$

The best-response mapping can also be defined in the space of CCPs as $\alpha_t^{BR}(\mathcal{M}_{j,i,t}, \epsilon_{it}, \mathbf{P}) = \arg \max_{a_{it} \in A(n_{it})} \{v_i^{\mathbf{P}}(a_{it}, \mathcal{M}_{j,i,t}) + \epsilon_{it}(a_{it})\}$ and a MPE can be represented as a fixed point of the best-response mapping (Aguirregabiria and Mira (2007), Pesendorfer and Schmidt-Dengler (2008))

$$\Phi_{i,t}(a_{it}|\mathcal{M}_{j,i,t}, \mathbf{P}) = \int 1 \left(a_{it} = \arg \max_{a_{it} \in A(n_{it})} \{v_{i,t}^{\mathbf{P}}(a_{it}, \mathcal{M}_{j,i,t}) + \theta^\epsilon \epsilon_{it}(a_{it})\} \right) dG(\epsilon_{it}).$$

If private shocks are distributed Type 1 extreme value (with scale parameter θ^ϵ), an optimal strategy for firm i will map into conditional choice probabilities of the form

$$P_t(a_{it}|\mathcal{M}_{j,i,t}, \mathbf{P}) = \frac{\exp\left(\frac{v_{i,t}^{\mathbf{P}}(a_{it}, \mathcal{M}_{j,i,t})}{\theta^\epsilon}\right)}{\sum_{a' \in A(n_{it})} \exp\left(\frac{v_{i,t}^{\mathbf{P}}(a', \mathcal{M}_{j,i,t})}{\theta^\epsilon}\right)}. \quad (19)$$

Simultaneity in players' moves can cause multiplicity of equilibria in this context. The two CCP-based estimation approaches we use circumvent this difficulty by relying on the best-response mapping as estimating equations (Pesendorfer and Schmidt-Dengler (2008),

Kalouptsidi et al. (2020), Bugni and Bunting (2021)). For our counterfactual analysis, we initialize the computation algorithm at a large number of starting values and iterate to a fixed point. We found no evidence of multiple equilibria in the counterfactual exercise.

Finite dependence The model features a terminal choice—exit without the possibility of re-entry—a special case of finite dependence (Altuğ and Miller (1998), Arcidiacono and Miller (2011)). Finite dependence eases the calculation of ex-ante and choice-specific value functions because these can be expressed directly in terms of the period-ahead probabilities of choosing the terminal choice. Moreover, it allows us to incorporate nonstationarities into the model without making out-of-sample assumptions about players’ actions for periods beyond the sample horizon (which is the year 2019).

Single-store firms If a single-store incumbent exits or a single-store potential entrant stays out, the continuation value is zero. The choice-specific value function from staying active (either entering or remaining in the market) can therefore be expressed relative to the exit choice, denoted e (for an incumbent, it is $a_{it} = l_-$ if $n_{ilt} = 1$, or for a potential entrant $a_{it} = 0$). The choice-specific value function (Equation (17)) can be rewritten for all $a_{it} \neq e$

$$v_{i,t}^{\mathbf{P}}(a_{it}, \mathcal{M}_{j,i,t}) = \pi_i(a_{it}, \mathcal{M}_{j,i,t}) + \beta \sum_{a_{-it}} \int [v_{i,t+1}^{\mathbf{P}}(a'_i = e, \mathcal{M}_{j,i,t+1}) + \gamma - \ln(P_{i,t+1}(e|\mathcal{M}_{j,i,t+1}))] dF_t(\mathcal{M}_{j,i,t+1}|\mathcal{M}_{j,i,t}, a_t) P_{-i,t}(a_{-it}|\mathcal{M}_{j,i,t}) \quad (20)$$

where γ is the Euler constant. The choice-specific value function corresponding to the exit decision is given by

$$v_{i,t+1}^{\mathbf{P}}(a'_i = e, \mathcal{M}_{j,i,t+1}) = \begin{cases} \pi_i(a'_i = e, \mathcal{M}_{j,i,t+1}) & \text{if } i \text{ is an incumbent in } l \\ 0 & \text{if } i \text{ is potential entrant} \end{cases}$$

Multi-store firms. The problem for multi-store entrants differs from that of single-store ones because chains are long-lived: they can delay entry into a market without being replaced by a new potential entrant. Therefore, the only terminal choice for a multi-store firm is exit from incumbency. Because multi-store firms are restricted to close or open only one store per period, exit can occur only when the firm is operating a single store. Finite dependence still holds, but in the number of periods it takes to bring the firm to operating a single-store in the market. For instance, a firm operating three stores in period t and choosing to do nothing will be in a state that features three-period finite dependence.

For an incumbent operating a single-store in location l ($a_{it} = 0$) or a potential entrant

i who enters into location l ($a_{it} = l_+$), the choice-specific value function is identical to Equation (20).

For potential entrant i who stays out in period t , that is $a_{it} = 0$, the choice-specific value function can be expressed, given entry into an arbitrary location $a'_i = l_+$ in period $t + 1$ as follows

$$\begin{aligned}
v_{i,t}^{\mathbf{P}}(0, \mathcal{M}_{j,i,t}) &= \pi_i(0, \mathcal{M}_{j,i,t}) + \beta \sum_{a_{-it}} \int [v_{i,t+1}^{\mathbf{P}}(a'_i = l_+, \mathcal{M}_{j,i,t+1}) + \gamma \\
&\quad - \ln(P_{i,t+1}(l_+ | \mathcal{M}_{j,i,t+1}))] dF_{\mathcal{M}_{j,i,t+1} | \mathcal{M}_{j,i,t}} P_{-i,t} \\
&= \pi_i(0, \mathcal{M}_{j,i,t}) + \beta \sum_{a_{-it}} \int ([\pi_i(l_+, \mathcal{M}_{j,i,t+1}) + \gamma - \ln(P_{i,t+1}(l_+ | \mathcal{M}_{j,i,t+1}))] \\
&\quad + \beta^2 \sum_{a_{-i,t+1}} \int [v_{i,t+2}^{\mathbf{P}}(a''_i = l_-, \mathcal{M}_{j,i,t+2}) + \gamma - \ln(P_{i,t+2}(l_- | \mathcal{M}_{j,i,t+2}))] \\
&\quad \times dF_{\mathcal{M}_{j,i,t+2} | \mathcal{M}_{j,i,t+1}} P_{-i,t+1}) dF_{\mathcal{M}_{j,i,t+1} | \mathcal{M}_{j,i,t}} P_{-i,t}
\end{aligned} \tag{21}$$

The last equality shows that in period $t + 2$, one can obtain an expression for the ex-ante value function by choosing the exit choice $a''_i = l_-$.²⁵

5 Estimation of the Dynamic Game

5.1 Market Definition for the Dynamic Game

In our structural analysis, we restrict the sample to small and medium-sized isolated markets for several reasons. First, due to their relatively small number of stores, these markets are most impacted by closure of an existing store. This makes such markets more susceptible to issues of food accessibility. Second, when accounting for spatial differentiation, computational reasons limit the size of markets for which we can solve the dynamic game. Following

²⁵More generally, for an incumbent chain operating a network of stores \mathbf{n}_{it} and choosing action a in period t , define a sequence of choices $\{a_{t+\tau}\}_{\tau=1}^{|\mathbf{n}_{it}+a|}$, such that in every period $t + \tau$, the chain closes one of its operating stores. Then, the choice-specific value function can be expressed as follows ($|\mathbf{n}_{it} + a| + 1$ finite dependence)

$$\begin{aligned}
v_{i,t}^{\mathbf{P}}(a, \mathcal{M}_{j,i,t}) &= \pi_i(a, \mathcal{M}_{j,i,t}) + \sum_{\tau=1}^{|\mathbf{n}_{it}+a|-1} \beta^{\tau-1} \mathbb{E}[\pi_i(a_{i,t+\tau}, \mathcal{M}_{j,i,t+\tau}) - \ln(P_{i,t+\tau}(a_{i,t+\tau} | \mathcal{M}_{j,i,t+\tau})) | \mathcal{M}_{j,i,t}] \\
&\quad + \beta^{|\mathbf{n}_{it}+a|} \mathbb{E}[v_{i,t+|\mathbf{n}_{it}+a|}^{\mathbf{P}}(a = e, \mathcal{M}_{j,i,t+|\mathbf{n}_{it}+a|}) - \ln(P_{i,t+|\mathbf{n}_{it}+a|}(e | \mathcal{M}_{j,i,t+|\mathbf{n}_{it}+a|}))]
\end{aligned} \tag{22}$$

Seim (2006), we define markets as cities and incorporated places with populations between 5,000 and 150,000, and exclude markets within 10 miles of a city with population greater than 5,000 or within 20 miles of a city with population greater than 25,000. Each market is partitioned into locations, which we define at the census tract level.²⁶

The above market definition is motivated by our focus on competition between the dollar store chains and independent grocery stores and convenience stores. The previous literature on retail competition has shown that competition between grocery stores operates at relatively close range (1–2mi). We exclude gas stations, drugstores, and supermarket chains from the set of players. In the case of supermarkets and big box retailer, previous literature (Ellickson and Grieco (2013), Grieco (2014)) has shown that their impact on small horizontally differentiated retailers is limited. Nonetheless, we do control for the presence of the latter three formats (gas stations, drugstores, supermarkets) as potential determinants in players’ payoffs, but will treat their evolution as exogenous.

Table 10 shows market and location-level demographic characteristics for our sample of 846 markets and Table 11 shows statistics on their market structure. These markets are small in terms of population and with low average incomes. Average income per capita is \$20,352 compared to roughly \$58,000 for the U.S. as a whole. A market contains 5.8 locations in total, 4.3 of which are “commercial” location while the remainder are “residential.” We define “commercial” locations as locations in which at least one store (of any type, e.g., dollar store, gas stations, drugstores, supermarkets) was active in any year between 2008 and 2019.

A typical market contains 2 dollar stores, 1 grocery store, 3 convenience stores, 2 gas stations, and 3 supermarkets, but with wide variation across markets. We note the relatively high number of supermarkets given our market definition. Close examination of the data reveals that supermarkets’ catchment areas are in general much larger than our definition of a market (i.e., census place). Our market definition is motivated by a focus on spatial competition between dollar stores and other small retailers. For supermarkets, markets are usually defined at larger geographic units, e.g., at the county or MSA level.

5.2 Identification

As is standard in the literature on the identification of dynamic decision problems (Rust (1994), Magnac and Thesmar (2002), Bajari et al. (2015)), the discount factor and the

²⁶Census tracts may cross the boundaries of a census place (city or town), in such instances, we define a location as the intersection between the census tract and the census place. These intersections are obtained using the Census Bureau’s geographic correspondance engine Georr. See <https://mcdc.missouri.edu/applications/geocorr2014.html>.

Table 10: Descriptive Statistics: Markets and Locations (2010-2019)

Variable	Mean	Median	Std.Dev	Min	Max
<i>Market-level characteristics</i>					
Population	14,146	10,430	11,714	3,160	124,950
Income per capita (past 12 months)	20,352	19,779	4,617	7,796	86,593
Residential rents	624.8	593.6	135.8	318.1	1,801.0
Land area (sq mi)	15.2	10.1	20.0	1.6	301.7
Distance to closest distribution center (mi)	262.7	188.2	188.6	31.6	1,132.3
Number of locations	5.8	5.0	4.3	1.0	30.0
Number of commercial locations	4.3	3.0	3.2	1.0	28.0
Observations (Market-Year)	8,460				
<i>Location-level characteristics</i>					
Population	2,435	2,327	1,953	1	13,586
Income per capita (past 12 months)	21,121	20,546	6,661	2,183	112,495
Residential rents	640.6	611.7	161.4	189.4	2,134.7
Land area (sq mi)	2.6	1.6	5.5	0.0	165.0
Observations (Market-Location-Year)	49,150				

Note: Distance to closest distribution center is the average over the top three chains. "Number of locations" corresponds to both residential and commercial locations. Commercial locations are those in which at least one store (including gas stations, drugstores, and supermarkets) was active in any year between 2008 and 2019.

Table 11: Descriptive Statistics: Stores (2010-2019)

Variable	Mean	Median	Std.Dev	Min	Max
<i>Market-level characteristics</i>

Observations (Market-Commercial Location-Year)	36,230				

distribution of firm shocks (β, G) are assumed to be known.²⁷

Aguirregabiria and Suzuki (2014) study the identification of market entry and exit games. They show that the level of fixed costs, entry costs and exit value are not separately identified.²⁸ When estimating the model, we normalize the exit value to zero. A consequence of this “normalization” restriction is that the estimated entry costs will reflect the true *sunk* costs (entry cost net of exit value), and estimated fixed costs will reflect the true fixed costs in addition to the exit value scaled by $(1 - \beta)$.

Variable profits are identified from exogenous variation in market and location-level characteristics (i.e., income, population, rents) and the geographic layout of markets (i.e, the distance between each pair of locations in a market) creating variation in these exogenous variables by distance bands around each location. The effects of rivals’ stores on profits (i.e., competitive effects) are identified in two ways: for chains, we rely on exogenous variation in the distance to the closest (rival) distribution center which shifts rival chains’ entry decisions without directly affecting own variable profits; for single-store firms, competitive effects are identified from variation in the incumbency status of rival single-store firms.

5.3 Estimation Approach

5.3.1 Baseline approach

We follow a two-step approach. In a first step, consistent estimates of the CCPs, denoted $\hat{\mathbf{P}}_0$ are obtained. We discuss this first step and the treatment of unobserved heterogeneity in detail in Section 5.3.2. In the remainder of this section, we focus on the estimation of the structural parameters given first-step estimates of the CCPs.

Existing methods for the estimation of dynamic games include policy evaluation (Aguirregabiria and Mira (2007), Pesendorfer and Schmidt-Dengler (2008)) or forward simulation (Bajari et al. (2007)). In our setting, however, firms’ dynamic locational choices within a market and the presence of multi-store firms generate a high-dimensional state space. Implementing these approaches would require a combination of state space discretization, approximation of the value functions, and numerical integration over the state space.

We tackle these challenges in two ways. First, we leverage the finite dependence property (Arcidiacono and Miller (2011, 2019)). In our setting, firms have a terminal choice (exit without the possibility of re-entry), a special case of finite dependence. As detailed in Section 4, this allows us to express period- t choice-specific value function as a function of period- $t + 1$

²⁷Markets are independent, therefore, identification is based on a cross-section of market-paths assuming they all feature the same equilibrium.

²⁸More recent contributions include Kalouptsi et al. (2021b) and Kalouptsi et al. (2021a).

(known) CCPs and structural profit function. Second, we avoid numerical integration over the high-dimensional state space by using the linear IV regression approach of Kalouptside et al. (2020). The latter paper combines insights from the finite dependence approach and the GMM-Euler approach (Aguirregabiria and Magesan (2013, 2018)) to construct moment restrictions for the structural parameters. These moment restrictions do not require explicit integration over the state space but only averaging over the sample observations. Estimation of the structural parameters amounts to a linear regression equation which substantially eases the computational burden.

We show that the estimator of Kalouptside et al. (2020) developed for *single-agent* dynamic discrete choice problems can be extended to dynamic games. As far as we know, this is the first application of the linear regression estimation approach to dynamic games. In dynamic games with simultaneous moves, a focal firm i 's decision in period t affects rivals' decisions in $t + 1$ and their endogenous states in $t + 2$: this aspect of games, absent in single-agent models, creates a dynamic selection problem for endogenous states. For instance, the number of grocery stores operating in location l at time $t + 2$ will depend on a dollar store chain's entry and exit decisions in period t (in the data).²⁹ The estimator of Kalouptside et al. (2020) is modified to account for this selection problem and obtain consistent estimates of the structural parameters. Next, we discuss how moment restrictions are constructed for single-store and multi-store firms.

Single-store firms. Differences in choice-specific value function for potential entrants and incumbents can be derived as follows. A potential entrant can either stay out ($a_{it} = 0$) or enter by building a store in any of the locations ($a_{it} = l_+$). The corresponding choice-specific value functions are given by

$$v_{i,t}^{\mathbf{P}}(a_{it} = 0, \mathcal{M}_{j,i,t}) = 0 \quad (23)$$

$$v_{i,t}^{\mathbf{P}}(a_{it} = l_+, \mathcal{M}_{j,i,t}) = -\theta_i^{EC} + \beta \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i + \gamma - \ln(P_{i,t+1}(l_-|\mathcal{M}_{j,i,t+1}))] \quad (24)$$

where the expectation is over $\mathcal{M}_{j,i,t+1}$ conditional on $(a_{it} = l_+, \mathcal{M}_{j,i,t})$ and we use finite dependence to express the entrant continuation value in period $t + 1$. Combining these two equations gives

²⁹Note due to simultaneous moves, a firm's action in t impacts rivals' states in $t + 2$ but not in $t + 1$.

$$v_{i,t}^{\mathbf{P}}(l_+, \mathcal{M}_{j,i,t}) - v_{i,t}^{\mathbf{P}}(0, \mathcal{M}_{j,i,t}) = -\theta_i^{EC} + \beta \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i + \gamma - \ln(P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1}))] \quad (25)$$

Differences in choice-specific value functions can alternatively be expressed using current period CCPs as

$$v_{i,t}^{\mathbf{P}}(l_+, \mathcal{M}_{j,i,t}) - v_{i,t}^{\mathbf{P}}(0, \mathcal{M}_{j,i,t}) = \ln \left(\frac{P_{i,t}(l_+ | \mathcal{M}_{j,i,t})}{P_{i,t}(0 | \mathcal{M}_{j,i,t})} \right) \quad (26)$$

Combining Equation (25) and Equation (26), we obtain an optimality condition that involves only CCPs at t and $t + 1$ and the single-period payoff function

$$\ln \left(\frac{P_{i,t}(l_+ | \mathcal{M}_{j,i,t})}{P_{i,t}(0 | \mathcal{M}_{j,i,t})} \right) = -\theta_i^{EC} + \beta \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i + \gamma - \ln(P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1}))] \quad (27)$$

This equation includes expected profits and CCPs at $t + 1$, and therefore, it appears that numerical integration over the state space is required. However, the equation can be used to construct moment conditions that do not require explicit integration over the space of state variables. Under rational expectations, the conditional expectation at period t of CCPs and profits at $t + 1$ is equal to these variables minus an expectational error that is orthogonal to the state variables at period t .³⁰ Therefore, for any function of period- t information set $h(\mathcal{M}_{j,i,t})$, we have

$$\mathbb{E}[h(\mathcal{M}_{j,i,t})u_{it}] = 0 \quad (28)$$

where u_{it} is the expectational error (also known as forecast error). It is defined, for any realization $\mathcal{M}_{j,i,t+1}^*$ of the random variable $\mathcal{M}_{j,i,t+1}$ as

$$\begin{aligned} u_{it}(\mathcal{M}_{j,i,t+1}^*) &= \beta \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i + \gamma - \ln(P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1})) \\ &\quad - \beta (vp_{i,l}(\mathcal{M}_{j,i,t+1}^*) - FC_i + \gamma - \ln(P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1}^*))) \\ &= \ln \left(\frac{P_{i,t}(l_+ | \mathcal{M}_{j,i,t})}{P_{i,t}(0 | \mathcal{M}_{j,i,t})} \right) + \theta_i^{EC} \\ &\quad - \beta (vp_{i,l}(\mathcal{M}_{j,i,t+1}^*) - FC_i + \gamma - \ln(P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1}^*))) \end{aligned} \quad (29)$$

³⁰This idea has been first used in the estimation of continuous choice dynamic structural models using Euler equations (e.g., Hansen and Singleton (1982)).

where the second equation is obtained by using the expression in Equation (27) to eliminate the expectation term. The moment conditions (Equation (28)) do not require integration over the space of state variables but only averaging over the sample observations. The computational cost of estimating the structural parameters using GMM based on these moment conditions does not depend on the dimension of the state space.

Kalouptsidei et al. (2020) show that, under linearity of payoffs, these moment conditions (replaced by their sample counterparts) can form the basis of a linear IV regression, where period- t variables are used as instruments for period $t + 1$ variables.³¹ Define the left-hand side variable for potential entrant and incumbent (respectively) as³²

$$Y_{it}^{entrant} = \ln \left(\frac{P_{i,t}(l_+ | \mathcal{M}_{j,i,t})}{P_{i,t}(0 | \mathcal{M}_{j,i,t})} \right) - \beta(\gamma - \ln(P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1})))$$

$$Y_{it}^{incumbent} = \ln \left(\frac{P_{i,t}(0 | \mathcal{M}_{j,i,t})}{P_{i,t}(l_- | \mathcal{M}_{j,i,t})} \right) - \beta(\gamma - \ln(P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1})))$$

We can obtain the structural parameter via the regression model

$$Y_{it}^{entrant} = -\theta_i^{EC} + \beta [vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i] + u_{it}$$

$$Y_{it}^{incumbent} = \beta [vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i] + u_{it}$$

where regressors entering the variable profit function in $t + 1$ $vp_{i,l}(\mathcal{M}_{j,i,t+1})$ (population, income, etc.) are instrumented using the values of these regressors in period t .

Multi-store firms. The estimation procedure for multi-store chains is conceptually similar but somewhat more complicated due to the fact that they are long-lived and can delay entry. This implies that finite dependence holds in two (or more) periods. In dynamic games, a focal firm i 's action in period t will affect its rivals' actions in $t + 1$ and their states in $t + 2$. This creates a selection problem in the data: endogenous state variables in period $t + 2$ are observed only conditional on the action a_{it} played by firm i in the data. We show, in Appendix A, that an appropriate reweighting using CCP ratios addresses the selection bias, extending the approach of Kalouptsidei et al. (2020) from single-agent to dynamic games.

To evaluate the robustness of our results, we also implement an alternative estimation

³¹The endogeneity problem occurs because $t + 1$ covariates may correlate with forecast errors. One can use instruments in the contemporaneous information set at t for these next-period covariates.

³²An incumbent single-store firm chooses between staying active ($a_{it} = 0$) or exiting ($a_{it} = l_-$). Differences in the choice-specific value function are given by

$$v_{i,t}^P(0, \mathcal{M}_{j,i,t}) - v_{i,t}^P(l_-, \mathcal{M}_{j,i,t}) = \beta \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i + \gamma - \ln(P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1}))] \quad (30)$$

where period- t profits cancel out.

approach, in [Appendix B](#), that does not rely on finite dependence and instead solves directly for the ex-ante value function.

5.3.2 Location-level unobserved heterogeneity and first-step estimates

The presence of unobserved heterogeneity is a common concern in many empirical settings and can introduce an endogeneity problem in the context of dynamic games of market entry and exit as it leads to biased estimates of competition. If unobserved heterogeneity is not controlled for, firms may appear to favor locations and markets with large numbers of competitors, which ultimately will yield economically implausible estimates of competitive effects.

We incorporate location-level unobserved heterogeneity via a proxy variable. This approach has been used in previous studies of market entry, e.g., [Collard-Wexler \(2013\)](#), and has the advantage of being computationally light. This is particularly important as a market is partitioned into multiple locations, which may differ in their attractiveness, yielding multi-dimensional unobserved heterogeneity. The proxy variable strikes a balance between granularity in the level of unobserved heterogeneity and computational feasibility. We define a location-level proxy for unobserved heterogeneity as the maximum number of establishments (of all types, including drugstores, supermarkets, and gas stations) *simultaneously* operating in a given location over the period 2008-2019.³³

The importance of controlling for unobserved heterogeneity is illustrated in [Table 12](#).³⁴ This table shows estimates of the CCPs for dollar store chains via a flexible multinomial logit regression. An entrant chain can either build a store in one of the locations in the market or stay out. An incumbent chain can do nothing, build an additional store in one of the locations, or close one of its existing stores.³⁵ We control for location-level demographic variables, cost shifters (e.g., the distance between the market and the closest distribution center), the location-level competitive environment, and market-level characteristics (e.g., other store types such as gas stations and supermarkets). We allow the parameters to differ for the decision to open and close a store. The first two columns correspond to a

³³The use of a proxy variable shares similarities with the control function method ([Wooldridge \(2015\)](#), for a recent overview). In our setting, the number of rival stores operating in location l at time t is correlated with the unobserved heterogeneity term, inducing an endogeneity problem. If there is a monotonic relationship between (persistent) location-level unobserved heterogeneity and the maximum number of stores operating in a location, then one can think of the latter variable as proxying for the unobserved heterogeneity factors (amenities such as available parking, access to busy thoroughfare), that are correlated with the number of rival stores operating in location l at time t .

³⁴In an ideal world, CCP would be estimated nonparametrically, but this is not possible given the size of the state space, the large number of choices that each firm has, and the size of the observed sample.

³⁵The small number of observations where a chain opens more than one store in a period are not included when calculating the likelihood.

specification without unobserved heterogeneity. The last two columns include the proxy for unobserved heterogeneity (“Business Density”). To allow strategies to depend on the roll-out of distribution centers, we also include year dummies.

The effect of competition on the likelihood of building a store are biased upward when business density is not controlled for (column 2) relative to when it is included (column 4). In column 2, many competition coefficients are in fact positive (e.g., for the number of grocery stores and convenience stores within 2mi), reflecting agglomeration effects due to unobserved location-level amenities. This is not the case when location-level business density is included (column 4). As a secondary test of the robustness of the proxy variable strategy, we recompute the reduced form results from section 3 but removing the location and market-year fixed effects and including the business density measure. Results are shown in Table A5 in Appendix E. We find that compared to the benchmark results, dropping fixed effects does generate an upward bias in the relationship between the number of dollar store entries and the number of independent grocery stores, but that when business density is included the effects are again negative and similar in magnitude to our preferred specification.

Similarly to chains, we estimate the CCP for single-store firms (grocery/combination stores and convenience stores) via flexible multinomial logit regressions, controlling for business density. We include the regression results in Appendix E for completeness.

6 Estimation Results

This section presents our estimates of the structural parameters entering single-period payoffs for dollar store chains, independent grocery, and convenience stores. Of particular interest are the magnitude of strategic interactions across store formats, the presence and size of economies of density or cannibalization, and the role of chains’ expanding network of distribution centers in driving the reduction in store operating costs.

Table 13 shows estimates of normalized store profits and entry costs. We include a constant term in the profit function to capture the level of fixed costs and/or any baseline level of profits. The effect of most variables decays with distance from the store location, highlighting the importance of spatial differentiation in retail competition. For all retailers, profits are increasing with the population within 2 miles of the store location. Dollar store chains favor locations with lower income. Profits for chains are decreasing in the distance to the closest distribution center. The majority of competition effects are precisely estimated and with the expected magnitude.

To help interpretation, we convert our profit estimates into dollars by calibrating the scale parameter of firm shocks θ^e to match revenue data for all dollar stores operating in the

Note: Standard errors are clustered by market. The baseline alternative is “do nothing.” Dollar figures are in 2010\$. Business density is defined as the maximum number of establishments simultaneously operating in location l over the period 2008-2019. Distance to distribution center is at the market level, residential rent is at the location level. All continuous variables and store counts are in log.

markets under consideration, obtained from Nielsen TDLinx.³⁶ Table 14 shows mean store profits and entry costs expressed in 2010\$, as well as marginal effects.

We find that, consistent with anecdotal reporting on dollar store growth, dollar store chains have substantially lower costs of opening a new store than their independent rivals.

³⁶Specifically, we convert the revenue data into profits (deflated to 2010), assuming a 5% net profit rate, and calibrate the scale parameter θ^ϵ to match the model-predicted profits and the observed profits for all operating dollar stores in 2019. We use the calibrated scale parameters to convert all estimates into 2010\$. For many stores, revenue data is imputed by Nielsen. Due to these imputations and the absence of revenue data for single-store firms, we do not use these data to estimate a demand model. This conversion is only used for interpretation purposes and is not used in the counterfactuals that follow.

One additional rival grocery/combination store (2-5 mi)	-10.14	-16.24	-8.18
One additional rival convenience store (0-2 mi)	-10.22	-24.78	-13.22
One additional rival convenience store (2-5 mi)	3.69	-2.90	-1.09
One additional own chain store (0-2 mi)	-13.15		
One additional own chain store (2-5 mi)	10.67		
Increase in dist. to distribution center by one s.d. from mean	-6.13		

Note: Averages are over all incumbent stores (for profits) and entrants (for entry costs) over the period 2010-2019. Conditional profits and entry costs include the expectation of the structural shock. Percentage changes are relative to the monopoly case. The mean distance to the closest distribution center is 190mi and the standard deviation is 130mi.

They are also substantially more profitable. When we examine the competitive effects of nearby rivals on profits, several results stand out. First, grocery store profits are significantly harmed by the presence of nearby dollar stores and convenience stores, with most of the effects for stores in the 0-2mi radius.³⁷ Second, the presence of dollar stores also significantly harms convenience store profits, by as much as an additional convenience store. Third, within dollar store chains, in the 0-2mi radius, there is a strong demand cannibalization effect but in the 2-5mi range this effect is reversed and chains benefit from scale economies, likely working through lower operating costs. The location of the market relative to a chain’s closest distribution center is also an important determinant of profits. We find that a one standard deviation increase (130mi) from the mean distance (190mi) raises operating costs and reduces store profits by 6.13%.

We also implement alternative specifications for chains’ dynamic investment costs. In particular, chains may benefit from network economies at the regional level by operating multiple stores in neighboring markets, which can reduce distribution and restocking costs (Jia (2008), Holmes (2011)). To capture these economies of density at the regional level, we allow the entry cost of the first store in the “region” (defined as a 100mi radius around the focal market) to differ from the entry cost of subsequent stores. The results are shown in Table A7 in Appendix E, which compares our baseline specification to the alternative described above. We find that the entry cost of the first store in the region is approximately twice as large as the entry costs of subsequent stores (4.68 versus 2.31). These estimates suggest that entry costs are drastically reduced when stores are opened near existing regional distribution networks, consistent with the previous literature studying Walmart’s expansion strategy.³⁸

7 Counterfactual Policy Analysis

This section uses the structural estimates to conduct counterfactual policy evaluations. We focus on evaluating the cumulative impact of dollar store expansion on market structure

³⁷The magnitude of the business stealing effects are consistent with anecdotal evidence from grocery store owners. For instance, the owner of the Foodliner store in Haven, KS reports,

“We lasted three years and three days after Dollar General opened,” he said. “Sales dropped and just kept dropping. We averaged 225 customers a day before and immediately dropped to about 175. A year ago we were down to 125 a day. Basically we lost 35 to 40% of our sales. I lost a thousand dollars a day in sales in three years.” (The Guardian, “Where even Walmart won’t go: how Dollar General took over rural America”, 2018)

³⁸Density economies may affect profits through both entry and fixed costs. Because the two effects cannot be separately identified, we capture density economies via entry costs.

and consumer-level outcomes by simulating the evolution of the industry had chains been prevented from expanding beginning in 2010. The counterfactual exercise allows us to quantify, first, the changes in the spatial distribution of retail stores induced by dollar stores’ expansion, and second, the changes in policy-relevant household outcomes, e.g. retail proximity and produce spending. By controlling for market heterogeneity, we can identify the distributional impacts of dollar store expansion for different market and consumer types. We outline in detail the method used to solve for counterfactual MPE in Appendix C.

7.1 The Impact on Spatial Market Structure

Table 15 shows how the expected number of grocery stores and convenience stores in 2019 are predicted to change in the counterfactual (CF) relative to the market equilibrium where dollar store chains expanded (Factual) by market. To obtain the factual and counterfactual market structures, we take the expectation over all possible realizations of spatial market structure given equilibrium factual and counterfactual CCPs. Due to computational limitations, we restrict the exercise to markets with up to 4 commercial locations.

We find that, in the hypothetical world in which dollar stores did not expand after 2010, markets have on average more than 50% more independent stores, including 54% more grocery stores and 47% more convenience stores. If scaled to all 846 markets we study, the net effect of these changes is that, without dollar store expansion, there would be roughly 482 more grocery stores and 747 more convenience stores at the cost of 721 dollar stores.

We also examine how these changes vary across different location types (see Table A8 in Appendix E). The largest impact on the number of grocery stores occurs in locations (census tracts) with lower income, larger shares of minority populations, higher poverty rates, and fewer households with access to vehicles. The effects are also largest in locations in which dollar stores did not already have a presence in 2010. For convenience stores, the increase in store counts is similar across market and location types.

7.2 The Impact on Consumer-Level Outcomes

Travel Costs In Table 16, we consider how changes in market structure translate into changes in retail proximity for households in 2019. All measures of retail proximity are constructed from data on population at the census block group, i.e., one level down from our definition of locations (census tract). Mean and median statistics are obtained by taking the (population-weighted) mean and median over all census block groups in a market.³⁹ Table 16

³⁹To compute distance to the nearest store, we assume that stores are located at the population-weighted centroid of their census tract. This assumption is required to keep the structural model tractable. We can,

Table 15: Expected number of stores by market

	Grocery/Combination store counts				Convenience store counts			
	Factual	CF	Δ	% Δ	Factual	CF	Δ	% Δ
All markets	1.079	1.657	0.578	0.544	2.094	2.978	0.883	0.474

<i>By presence of dollar stores in 2010</i>								
No dollar stores in 2010	1.041	1.67	0.629	0.65	1.901	2.762	0.861	0.534
Dollar stores present in 2010	1.087	1.654	0.567	0.521	2.135	3.023	0.888	0.461
<i>By presence of supermarkets in 2010</i>								
No supermarkets in 2010	1.266	1.889	0.623	0.512	1.795	2.576	0.781	0.496
Supermarkets present in 2010	1.072	1.648	0.576	0.545	2.106	2.993	0.887	0.473

Note: Factual corresponds to the expected number of stores under the market equilibrium. CF corresponds to the counterfactual expected number of stores. Δ (resp. % Δ) gives the difference (resp. percentage difference) between the market outcome and counterfactuals averaged over all markets. All demographic variables and store counts are at the market level.

shows the average distance between consumers and the nearest store, for the different retail formats, under the factual and counterfactual scenarios.

In panel A, we condition on the subset of markets in which there is at least one store format operating in both scenarios. The column $Pr(n > 0)$ gives the population-weighted probability that a market has at least one store of that format operating. The results suggest that the expansion of dollar store chains led to a reduction in “access to grocery stores,” in that 85% of markets contain a grocery store in the counterfactual, whereas in the factual only 70% do.

however, compare distances to the nearest store if the actual location (latitude and longitude) of each store in the factual scenario is used. Using population-weighted centroids instead of the actual store location does not quantitatively affect the results for the factual scenario.

In panels B and C, we use all markets, including those where no store is present in one of the scenarios. Because proximity is inherently not well-defined in these cases, we compute the upper (and lower) bounds on the distance to the nearest store by assuming a distance of 5 (and 7) miles if there are no stores operating in the market. We find that the distance to the nearest grocery store decreases by about 30% under the counterfactual scenario: from 2.30 to 1.68 miles (lower bound), or 2.91 to 2.00mi (upper bound). Given that prior research suggests consumers do not travel more than 1 or 2 miles for grocery trips, a change in average distance of .9 miles amounts to a significant increase in travel costs. By contrast, in the counterfactual without dollar store expansion, the distance to the nearest dollar store only increases by .18 miles, suggesting that relatively few consumers are harmed by losing convenient access to dollar stores.

Table 16: Predicted retail proximity: distance to nearest store

	Factual			Counterfactual		
	Mean	Median	$\Pr(n > 0)$	Mean	Median	$\Pr(n > 0)$
Panel A. Conditional on ($n > 0$)						
<i>Distance to nearest (in miles)</i>						
Grocery/Combination store	1.14	0.92	0.70	1.09	0.86	0.85
Convenience store	0.99	0.79	0.89	0.90	0.72	0.97
Dollar store	0.96	0.69	0.94	0.99	0.75	0.82
Any store format	0.80	0.62		0.81	0.62	
Panel B. All Markets (lower bound)						
<i>Distance to nearest (in miles)</i>						
Grocery/Combination store	2.30	2.35		1.68	1.56	
Convenience store	1.41	1.12		1.02	0.83	
Dollar store	1.21	0.74		1.73	0.92	
Any store format	0.88	0.67		0.84	0.66	
Panel C. All Markets (upper bound)						
<i>Distance to nearest (in miles)</i>						
Grocery/Combination store	2.91	3.02		2.00	1.81	
Convenience store	1.64	1.22		1.10	0.85	
Dollar store	1.34	0.74		2.10	0.92	
Any store format	0.92	0.67		0.86	0.66	

Note: Measures of retail proximity are constructed by taking the (population-weighted) mean and median over all census block groups. $\Pr(n > 0)$ gives the (population-weighted) mean probability that at least one store is operating in the market. Retail proximity to dollar stores is measured using actual realizations in the data in 2019 for Factual and in 2010 for Counterfactual. Unconditional panels assume that if there are no stores (of a given retail format) operating in the market, the distance travelled is 5mi (lower bound) or 7mi (upper bound).

Fresh Produce Spending Next, we study the cumulative effect of dollar store expansion on fresh produce spending, a central outcome in dollar store policy discussions. For this counterfactual exercise, we combine estimates from the household-level scanner data with the dynamic model of retail competition.

To predict changes in fresh produce spending, we proceed in two steps. First, we estimate the determinants of household-level fresh produce spending using the Circana Consumer Network panel, as in Section 3.2. In contrast to our reduced-form specification (Equation (3)), we include here the number of entries and exits by *every* retail format in a single regression and allow the effects to depend on household income. We estimate the following specification

$$Y_{ict} = \sum_k \delta_{k,i} Store_{k,bct} + \beta \mathbf{X}_{it} + \gamma_i + \eta_t + \epsilon_{ict} \quad (31)$$

where Y_{ict} is fresh produce spending by household i living in census tract c in period t , $Store_{k,bct}$ denote the number of store entries and exits by store type k (where k takes value in {dollar stores, grocery stores, convenience stores, supermarkets, and supercenters}) within distance band b from tract c by period t , \mathbf{X}_{it} are time-varying household characteristics, γ_i and η_t are household and time fixed effects. We allow the coefficients $\delta_{k,i}$ to differ for store entries and exits and to vary by household income.

Figure 7 presents the coefficients on dollar store entry and grocery store exit, within 0-2 miles, by household income. The results are aligned with those of Section 3.2, even with the larger set of market structure controls. The other coefficient estimates are also consistent with the findings of Allcott et al. (2019), i.e. we find null effects for entries of supermarkets, supercenters, and grocery stores.

Using the estimates from Equation 31, we calculate the difference in fresh produce spending between the factual and counterfactual MPE per census block group. The difference between the factual and counterfactual changes reflects the cumulative impact of dollar store expansion on fresh produce spending. Figure 8 presents histograms displaying the results. The left panel shows a significant reduction in fresh produce spending due to dollar store expansion in low-income census block groups, amounting to 6.18% of mean spending or 9.15% of median spending.⁴⁰ High-income census block groups, on the other hand, do not experience significant spending changes. The right panel of Figure 8 breaks down the effect by the level of vehicle access in the census block group. Although the average effects of dollar store expansion are greater in block groups with limited vehicle access, the magnitude of these effects is not as pronounced as those observed by block group income.

⁴⁰Average fresh produce spending for low-income households (bin 7 or lower) in the Circana Consumer Network panel over the sample period is \$97 per year, the median is \$65 per year.

Figure 7: The effect of the number of dollar store entries (left panel) and grocery store exits (right panel) on fresh produce spending (in dollars), by household income. Low income households are defined as households with annual income below \$45,000. High income households have income above \$45,000. Standard errors are clustered at the household level.

8 Conclusion

The rise of dollar store chains has profoundly reshaped the U.S. retail sector. By 2021, more than 75 percent of the U.S. population lives within five miles of a dollar store. This rapid expansion has been met with growing scrutiny from policymakers. Proponents claim that dollar stores broaden shopping options and improve convenience for consumers in underserved areas. Advocates of tighter controls argue that these chains threaten local independent stores, discourage entry by full-line grocery stores, and limit consumers’ access to fresh produce. In many municipalities, controls take the form of zoning ordinances that limit dollar store density.

Despite the existing public policy debates, there is little empirical evidence supporting the arguments advanced. This paper brings new data and methods to bear on these questions. We quantify the impacts of dollar stores’ expansion and the effects of entry regulation. Our focus is on two sets of outcomes. First, we consider spatial market structure, that is, the geographic layout and number of retail stores by format. This outcome is particularly important as it affects retail proximity, convenience, and product variety. Second, we consider consumers’ shopping behavior, including their spending across retail formats and food categories (e.g., fresh produce).

Our analysis demonstrates that dollar store entry leads to a significant reduction in the number of grocery stores, especially in close proximity (0–2mi) from the entry location. We find that markets lose one grocery store for every three new dollar stores. Dollar store entry and subsequent grocery store exits are associated with lower household spending and volumes purchased of fresh produce. Moreover, we highlight the distributional consequences of these

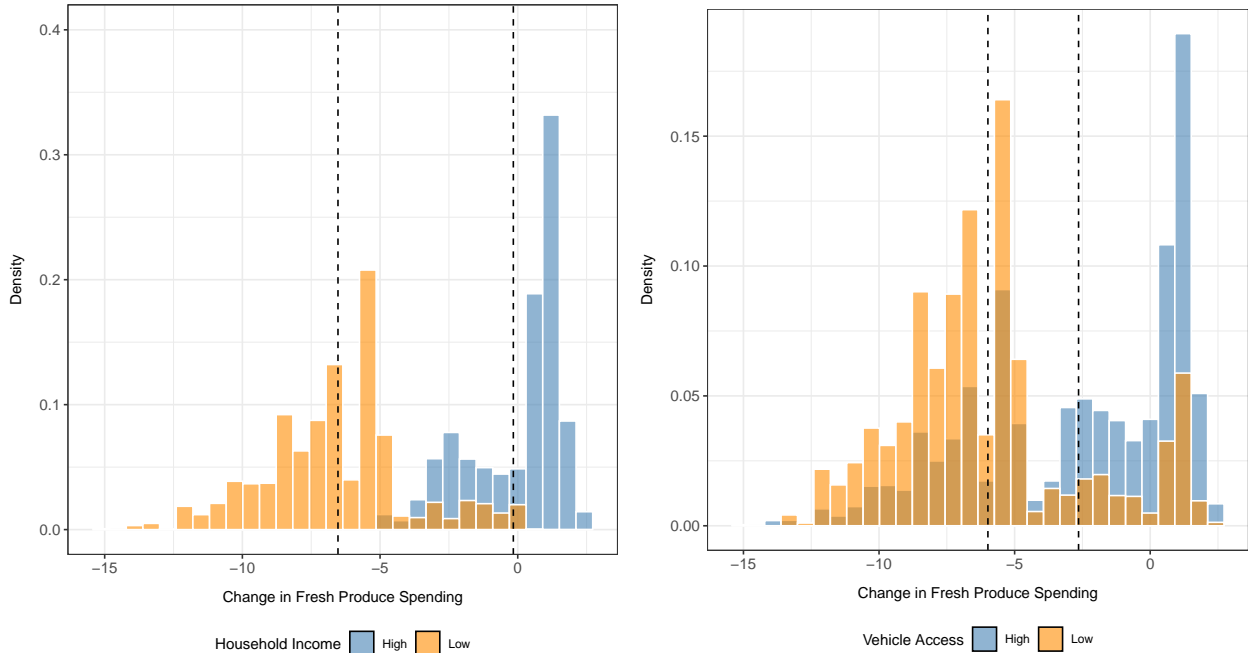

Figure 8: Counterfactual changes in fresh produce spending by census block group income (left) and access to vehicle (right). Low (resp. high) income is defined as census block groups with average annual household income below (resp. above) \$45,000. Low access to vehicle corresponds to census block groups where more than 15% of the households do not have access to a vehicle. The dashed vertical lines show weighted means (where the weights are the census block group population in 2019).

findings: fresh produce consumption and grocery access decrease most for consumers who initially tend to eat less healthfully and have higher transportation costs—low income, older, from minority groups, without access to a vehicle. Overall, we find that negative shocks to food availability have a meaningful impact on consumers’ dietary choices. These results add nuance to the literature on the determinants of nutritional inequality.

To better understand how the dollar store model grew so rapidly and the long-run effects of regulating entry, we specify a dynamic model of spatial competition between store formats. The model accounts for the growth in dollar stores’ network of distribution centers, and concomitant reduction in store operating costs. The spatial nature of competition introduces non-trivial complexities when estimating and solving this game. Methodologically, we deal with the high-dimensionality of the firms’ problem by extending the ECCP estimator of Kalouptsi *et al.* (2020) from single-agent problems to dynamic games.

Estimates indicate that dollar store chains benefit from lower entry costs and from operating at higher store density. Their increasingly wide network of distribution centers allows them to reduce store-level fixed costs over time and support their expanding retail footprint.

Independent grocery and convenience stores, on the other hand, are harmed by the presence of dollar stores at close proximity.

For small and medium-sized markets, our counterfactual exercise establishes that dollar store chains' expansion led to a significant reduction in the number of grocery stores, from 1.65 to just over 1 store per market. The largest impact occurs in lower income markets, those with larger shares of minority groups, those with higher poverty rates, and fewer households with access to a vehicle. In line with our reduced form findings, these changes in market structure are associated with significant reduction in fresh produce spending for households with low income and high travel costs.

The welfare implications of dollar store expansion are arguably multifaceted. Dollar store entry may affect consumer welfare through changes in prices (both at dollar stores and through their competitors' response), changes in store convenience (or travel costs), and changes in product availability and the ensuing composition of consumers' shopping baskets. In the medium to long-run, changes in consumers' dietary choices can have important implications for health outcomes. While the existing data and the many channels above prevent an estimation approach that accounts for all these dimensions in a single model, we view this paper as a necessary first step in quantifying this impact and informing the debate around the place of the dollar store format in the U.S. retail landscape.

A Estimation Approach for Multi-Store Firms

This section describes the baseline estimation approach for dollar store chains. Differences in choice-specific value functions for chains are derived as follows.

Potential entrants are long-lived and can delay entry into a later period (e.g., if a chain anticipates opening a distribution center closer to the market in the future). The choice-specific value functions from staying out and entering into location l are given, respectively, by

$$v_{i,t}^{\mathbf{P}}(0, \mathcal{M}_{j,i,t}) = \beta \mathbb{E} \left(-\theta_i^{EC} + \gamma - \ln P_{i,t+1}(l_+ | \mathcal{M}_{j,i,t+1}) \right. \\ \left. + \beta^2 \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+2}) - FC_i + \gamma - \ln P_{i,t+2}(l_- | \mathcal{M}_{j,i,t+2})] | 0, \mathcal{M}_{j,i,t} \right) \quad (32)$$

$$v_{i,t}^{\mathbf{P}}(l_+, \mathcal{M}_{j,i,t}) = -\theta_i^{EC} + \beta \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i + \gamma - \ln P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1}) | l_+, \mathcal{M}_{j,i,t}] \quad (33)$$

The first equation shows that, if an entrant stays out, they internalize the option value from entering at a later period. Differences in choice-specific value functions can alternatively be expressed using current period CCPs as

$$v_{i,t}^{\mathbf{P}}(l_+, \mathcal{M}_{j,i,t}) - v_{i,t}^{\mathbf{P}}(0, \mathcal{M}_{j,i,t}) = \log \left(\frac{P_{i,t}(l_+ | \mathcal{M}_{j,i,t})}{P_{i,t}(0 | \mathcal{M}_{j,i,t})} \right) \quad (34)$$

Combining Equation (32), Equation (33), and Equation (34), we obtain an optimality condition that depends only on the structural parameters and the known CCPs.

This optimality condition involves expectations over period $t + 1$ and $t + 2$ states. To avoid numerical integration over the high-dimensional state space, we dispose of the expectations by invoking the rational expectations assumption. Define the expectational errors as the difference between the expectations and the realizations of the random variables. For potential entrants who stay out, there are two expectations (over $t + 1$ and $t + 2$ states), therefore, the expectational errors ($w_{it}, u_{i,t+1}$) are defined as

$$w_{it} = \mathbb{E} \left[-\theta_i^{EC} + \gamma - \ln P_{i,t+1}(l_+ | \mathcal{M}_{j,i,t+1}) | 0, \mathcal{M}_{j,i,t} \right] \\ - \left(-\theta_i^{EC} + \gamma - \ln P_{i,t+1}(l_+ | \mathcal{M}_{j,i,t+1}) \right) \quad (35)$$

$$u_{i,t+1} = \mathbb{E} [vp_{i,l}(\mathcal{M}_{j,i,t+2}) - FC_i + \gamma - \ln P_{i,t+2}(l_- | \mathcal{M}_{j,i,t+2}) | 0, \mathcal{M}_{j,i,t}] \\ - (vp_{i,l}(\mathcal{M}_{j,i,t+2}) - FC_i + \gamma - \ln P_{i,t+2}(l_- | \mathcal{M}_{j,i,t+2})) \quad (36)$$

For potential entrants who enter (and become incumbents in $t + 1$), we define the expectational error v_{it} as

$$v_{it} = \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i + \gamma - \ln(P_{i,t+1}(l_-|\mathcal{M}_{j,i,t+1})|\mathcal{M}_{j,i,t}, l_+)] \\ - (vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i + \gamma - \ln(P_{i,t+1}(l_-|\mathcal{M}_{j,i,t+1}))) \quad (37)$$

These errors satisfy, for any function $g(\cdot)$ of period- t variable, the moment conditions:

$$\mathbb{E}[g(\mathcal{M}_{j,i,t})'[w_{it}, v_{it}, u_{i,t+1}]] = \mathbf{0}_3 \quad (38)$$

Replacing these moment conditions by their sample counterparts (in the form of a linear IV regression as in Kalouptsi et al. (2020)) will not, in general, yield consistent estimates of the structural parameters. Indeed, the error $u_{i,t+1}$ involves an expectation over $t+2$ states, denoted $\mathcal{M}_{j,i,t+2}$, conditional on $a_{it} = 0$. But the empirical distribution of $\mathcal{M}_{j,i,t+2}$ (in particular rivals' states) is conditional on the action a_{it} that was played in the data, which may or may not be 0.⁴¹⁴²

To address this selection problem, we define the weights

$$\psi_{a_1, a_2}(\mathcal{M}_{j,i,t+2}|\mathcal{M}_{j,i,t}) = \frac{P(\mathcal{M}_{j,i,t+2}|\mathcal{M}_{j,i,t}, a_{it} = a_1)}{P(\mathcal{M}_{j,i,t+2}|\mathcal{M}_{j,i,t}, a_{it} = a_2)} \quad (40)$$

Lemma 1. *Let $\mathcal{M}_{j,i,t+2}(\tilde{a})$ be the random vector of $t+2$ states conditional on $a_{it} = \tilde{a}$. Then, the (re-weighted) random variable*

$$\mathcal{M}_{j,i,t+2}(\tilde{a}) \times \psi_{0, \tilde{a}}(\mathcal{M}_{j,i,t+2}|\mathcal{M}_{j,i,t})$$

follows the distribution of $\mathcal{M}_{j,i,t+2}$ conditional on $a_{it} = 0$.

In constructing the sample moment counterparts, the data is reweighted using the CCPs ratio $\psi_{0, \tilde{a}}$ as follows. Define the re-weighted expectational error, for each $a_{it} = \tilde{a}$ as

$$\tilde{u}_{i,t+1} = \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+2}) - FC_i + \gamma - \ln P_{i,t+2}(l_-|\mathcal{M}_{j,i,t+2})|0, \mathcal{M}_{j,i,t}] \\ - \psi_{0, \tilde{a}}(\mathcal{M}_{j,i,t+2}|\mathcal{M}_{j,i,t}) (vp_{i,l}(\mathcal{M}_{j,i,t+2}) - FC_i + \gamma - \ln P_{i,t+2}(l_-|\mathcal{M}_{j,i,t+2})) \quad (41)$$

Defining the left-hand side variables for entrant chains as

⁴¹This selection problem only concerns $t+2$ rivals' states. In period $t+1$, rivals' states do not depend on a_{it} (conditional on the current state) because all firms take their actions simultaneously between t and $t+1$. Additionally, the selection problem does not concern exogenous variables (independent of a_{it}) or the firm's own state (a deterministic function of a_{it}).

⁴²To see why the exclusion restriction fails when $a_{it} = \tilde{a}$, note that

$$E[u_{i,t+1}|\mathcal{M}_{j,i,t}] = \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+2}) - FC_i + \gamma - \ln P_{i,t+2}(l_-|\mathcal{M}_{j,i,t+2})|0, \mathcal{M}_{j,i,t}] \\ - \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+2}) - FC_i + \gamma - \ln P_{i,t+2}(l_-|\mathcal{M}_{j,i,t+2})|\tilde{a}, \mathcal{M}_{j,i,t}] \quad (39)$$

equals zero only when $\tilde{a} = 0$.

$$\begin{aligned}
Y_{it}^{entrant} = & \log \left(\frac{P_{i,t}(l_+ | \mathcal{M}_{j,i,t})}{P_{i,t}(0 | \mathcal{M}_{j,i,t})} \right) \\
& - \beta[\gamma - \ln P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1})] \\
& + \beta[\gamma - \ln P_{i,t+1}(l_+ | \mathcal{M}_{j,i,t+1})] \\
& + \beta^2 \psi_{0,\bar{a}}(\mathcal{M}_{j,i,t+2} | \mathcal{M}_{j,i,t}) [\gamma - \ln P_{i,t+2}(l_- | \mathcal{M}_{j,i,t+2})]
\end{aligned} \tag{42}$$

we obtain the structural parameters for entrants via the regression model

$$\begin{aligned}
Y_{it}^{entrant} = & [-\theta_i^{EC} + \beta(vp_{i,l}(\mathcal{M}_{j,i,t+1}) - FC_i)] \\
& - [-\beta\theta_i^{EC} + \psi_{0,\bar{a}}(\mathcal{M}_{j,i,t+2} | \mathcal{M}_{j,i,t})\beta^2(vp_{i,l}(\mathcal{M}_{j,i,t+2}) - FC_i)] \\
& + (v_{it} - u_{it} - \beta\tilde{u}_{i,t+1})
\end{aligned} \tag{43}$$

where regressors entering the variable profit function in $t + 1$ and $t + 2$ are instrumented using the values of these regressors in period t .

For an incumbent chain with one store in location l^* , possible actions are to do nothing, build a second store, or close its existing store (note we allow the entry cost for the second store $\tilde{\theta}_i^{EC}$ to be different than for that of the first store θ_i^{EC}). The corresponding choice-specific value functions are given by

$$v_{i,t}^{\mathbf{P}}(l^*, \mathcal{M}_{j,i,t}) = vp_{i,l^*}(\mathcal{M}_{j,i,t+1}) - FC_i \tag{44}$$

$$\begin{aligned}
v_{i,t}^{\mathbf{P}}(0, \mathcal{M}_{j,i,t}) = & vp_{i,l^*}(\mathcal{M}_{j,i,t+1}) - FC_i \\
& + \beta \mathbb{E}[vp_{i,l^*}(\mathcal{M}_{j,i,t+1}) - FC_i + \gamma - \ln P_{i,t+1}(l_-^* | \mathcal{M}_{j,i,t+1}) | \mathcal{M}_{j,i,t}, 0]
\end{aligned} \tag{45}$$

$$\begin{aligned}
v_{i,t}^{\mathbf{P}}(l_+, \mathcal{M}_{j,i,t}) = & vp_{i,l^*}(\mathcal{M}_{j,i,t+1}) - FC_i - \tilde{\theta}_i^{EC} \\
& + \beta \mathbb{E}[vp_{i,l}(\mathcal{M}_{j,i,t+1}) + vp_{i,l^*}(\mathcal{M}_{j,i,t+1}) - FC_i \\
& + \gamma - \ln P_{i,t+1}(l_- | \mathcal{M}_{j,i,t+1}) | \mathcal{M}_{j,i,t}, l_+] \\
& + \beta^2 \mathbb{E}[vp_{i,l^*}(\mathcal{M}_{j,i,t+2}) - FC_i + \gamma - \ln P_{i,t+2}(l_-^* | \mathcal{M}_{j,i,t+1}) | \mathcal{M}_{j,i,t}, l_+]
\end{aligned} \tag{46}$$

We can derive two sets of optimality conditions (e.g., do nothing vs. build a second store, and do nothing vs. close an existing store), by taking differences in the choice-specific value functions and using their CCP representation

$$v_{i,t}^{\mathbf{P}}(l_+, \mathcal{M}_{j,i,t}) - v_{i,t}^{\mathbf{P}}(0, \mathcal{M}_{j,i,t}) = \log \left(\frac{P_{i,t}(l_+ | \mathcal{M}_{j,i,t})}{P_{i,t}(0 | \mathcal{M}_{j,i,t})} \right) \tag{47}$$

$$v_{i,t}^{\mathbf{P}}(0, \mathcal{M}_{j,i,t}) - v_{i,t}^{\mathbf{P}}(l^*, \mathcal{M}_{j,i,t}) = \log \left(\frac{P_{i,t}(0 | \mathcal{M}_{j,i,t})}{P_{i,t}(l_-^* | \mathcal{M}_{j,i,t})} \right) \tag{48}$$

As with entrants, we can dispose of the expectations using the rational expectation assumption and derive moment conditions. As before, period $t + 2$ states, appearing in Equation (46), are *conditional* on the action $a_{it} = l_+$. However, the empirical distribution of $\mathcal{M}_{j,i,t+2}$ is conditional on the a_{it} played in the data, which may or may not be l_+ . To correct for this selection problem in forming the IV regression equation, any term involving $\mathcal{M}_{j,i,t+2}$ is re-weighted using $\psi_{l_+, \tilde{a}}(\mathcal{M}_{j,i,t+2} | \mathcal{M}_{j,i,t})$, where \tilde{a} is the action played in the data.

B Alternative Estimation Approach

The baseline estimation approach extends the ECCP estimator of Kalouptsi et al. (2020) from single-agent problems to dynamic games. The estimator leverages the finite-dependence property to express ex-ante value functions as a function of (observed) CCPs, drastically reducing computational costs. A potential caveat of this estimator is that it places a sizeable burden on particular reference probabilities (e.g., the probability of exit). If these probabilities are not precisely estimated, this can introduce bias in the estimates of dynamic investment costs (e.g., entry costs). To alleviate these concerns, we compare our baseline estimation results to ones obtained using an alternative approach that does not rely on finite dependence but instead solves directly for the ex-ante value function.

As the state space is exceptionally large and some state variables are continuous, it is impossible to solve for value functions at all states. Therefore, we approximate the ex-ante value function by a linear parametric function of K variables at a pre-specified number of states N (including all states observed in the data). Value function approximation has been implemented in other studies such as Sweeting (2013), Aguirregabiria and Vicentini (2016), Jia Barwick and Pathak (2015), and Beresteanu et al. (2019). Following the notation in Sweeting (2013), we express the ex-ante value function as

$$\bar{V}_{i,t}^{\mathbf{P}}(\mathcal{M}_{j,i,t}) \approx \sum_{k=1}^K \lambda_k \phi_{ki}(\mathcal{M}_{j,i,t}) \quad (49)$$

In practice, approximating functions $\phi_{ki}(\mathcal{M}_{j,i,t})$ include all exogenous variables and number of rival and own stores by distance bands and locations.⁴³ We allow the coefficients λ_k to differ by firm type (e.g., convenience, grocery, dollar store) and by incumbency status.⁴⁴

Given a vector of CCPs and structural parameters in iteration (k), denoted $(\mathbf{P}^{(k)}, \boldsymbol{\theta}^{(k)})$, we iterate over the following steps.

⁴³For incumbents, we sum these approximating functions over all stores the firm is currently operating. For a single-store entrant, the continuation value of staying out is zero (terminal action); whereas the continuation value of entering is equal to the ex-ante value function of being an incumbent in period $t + 1$ (net of entry costs). By contrast, for a chain entrant, staying out is not a terminal action, therefore we also approximate the ex-ante value function of being an entrant, as the sum of exogenous and endogenous variables by distance bands over *all locations* in the market. We experimented with a saturated model including interactions, and/or market fixed effects, without significant improvements in fit. This is likely due to the fact that the static payoff function is linear.

⁴⁴Because there is a time-to-build (and to exit) of one period, current-period profits for incumbents only depend on the stores operated at the beginning of the period but not on the chosen action (remain active, exit, build an additional store) and cancel out when taking differences in choice-specific value function. To

1. Solve for the ex-ante value function for each player i , denoted \mathbf{V}_i . This is a vector stacking value functions at the N pre-specified states. Under our approximation, the value function can be expressed as $\mathbf{V}_i = \boldsymbol{\lambda}' \boldsymbol{\phi}_i$, in matrix form. In equilibrium, the ex-ante value function must satisfy the following identity,

$$\mathbf{V}_i = \boldsymbol{\lambda}' \boldsymbol{\phi}_i = \sum_a \mathbf{P}_i^{(k)}(a) \left[\boldsymbol{\pi}_i^{(k)}(a) + \mathbb{E}[\epsilon|a] \right] + \beta \boldsymbol{\lambda}' \mathbb{E}[\boldsymbol{\phi}_i] \quad (50)$$

where $\boldsymbol{\pi}_i^{(k)}(a)$ is the vector of current-period profits given structural parameters $\boldsymbol{\theta}^{(k)}$, $E[\epsilon|a]$ is the expected firm-specific shock given action a is chosen, and $\mathbb{E}[\boldsymbol{\phi}_i]$ is the expected future value of the approximating functions with component $\mathbb{E}[\phi_{ki}(\mathcal{M}_{j,i,t+1})|\mathcal{M}_{j,i,t+1}]$. Rewriting this identity as

$$\boldsymbol{\lambda}' (\boldsymbol{\phi}_i - \beta \mathbb{E}[\boldsymbol{\phi}_i]) = \sum_a \mathbf{P}_i^{(k)}(a) \left[\boldsymbol{\pi}_i^{(k)}(a) + \mathbb{E}[\epsilon|a] \right] \quad (51)$$

$\boldsymbol{\lambda}$ can be found by an OLS regression. To calculate $\mathbb{E}[\boldsymbol{\phi}_i]$, we fit an AR-1 process for each exogenous state variables (location-level population, income, and rents, in logarithm), allowing for innovation shocks that are correlated across locations in a market. For the endogenous states (store counts), we simulate 1,000 realizations of next-period spatial market structure by drawing from the current vector of CCPs $\mathbf{P}^{(k)}$.

2. Given estimates of the ex-ante value function, update the vector of choice-specific value functions for each player i , denoted $\mathbf{v}_i^{(k)}(a|\boldsymbol{\theta})$, as a function of a candidate vector of structural parameter $\boldsymbol{\theta}$

$$\mathbf{v}_i^{(k)}(a|\boldsymbol{\theta}) = \boldsymbol{\pi}_i(a|\boldsymbol{\theta}) + \beta \widehat{\boldsymbol{\lambda}}' \mathbb{E}[\boldsymbol{\phi}_i|a] \quad (52)$$

where $\boldsymbol{\pi}_i(a|\boldsymbol{\theta})$ are current-period profits parameterized as a function of candidate parameter $\boldsymbol{\theta}$, and $\mathbb{E}[\boldsymbol{\phi}_i|a]$ is the expected future value of the approximating functions given action a is played, that is, $\mathbb{E}[\phi_{ki}(\mathcal{M}_{j,i,t+1})|a, \mathcal{M}_{j,i,t+1}]$, which is calculated in a similar fashion as in the previous step (except for the additional conditioning on action a).

3. After pooling the data across all markets and periods, optimize the objective function with respect to the structural parameters. We implement a minimum-distance estimator (Pesendorfer and Schmidt-Dengler (2008), Bugni and Bunting (2021)). The distance between the initial CCPs and predicted CCPs (or alternatively between differences in choice-specific value functions) is minimized, that is,

be able to estimate profits, the ex-ante value function is, in practice, approximated as

$$\overline{\mathbf{V}}_{i,t}^{\mathbf{P}}(\mathcal{M}_{j,i,t}) \approx VP_i(\mathcal{M}_{j,i,t}) + \sum_{k=1}^K \lambda_k \phi_{ki}(\mathcal{M}_{j,i,t})$$

To keep the exposition concise, we ignore this first term in the derivation that follows.

$$\min_{\boldsymbol{\theta}} \left\| \log \left(\frac{\mathbf{P}_i^{(0)}(a)}{\mathbf{P}_i^{(0)}(a')} \right) - (\mathbf{v}_i^{(k)}(a|\boldsymbol{\theta}) - \mathbf{v}_i^{(k)}(a'|\boldsymbol{\theta})) \right\|_2$$

Denote $\boldsymbol{\theta}^{(k+1)}$ the updated structural parameters.⁴⁵

4. Update the CCPs, using the new structural parameters, that is,

$$\mathbf{P}_i^{(k+1)}(a) = \frac{\exp \left(\mathbf{v}_i^{(k)}(a|\boldsymbol{\theta}^{(k+1)}) \right)}{\sum_{\tilde{a}} \exp \left(\mathbf{v}_i^{(k)}(\tilde{a}|\boldsymbol{\theta}^{(k+1)}) \right)}. \quad (53)$$

The k -Minimum Distance (k -MD) estimator iterates on these steps k times. [Bugni and Bunting \(2021\)](#) show that the k -MD estimator is consistent and asymptotically normal for any $k \geq 1$, and for an initial choice of CCPs that is asymptotically equivalent to the frequency estimator (e.g., flexible logit) and a specific optimal weight matrix, the 1-MD estimator is optimal.

[Table A1](#) shows estimates of the structural parameters based on our baseline estimator (ECCP with finite dependence) and the 1-MD estimator presented above, using the sample of 846 markets. The two approaches yield very close estimates of entry costs, and profit parameters that are broadly of similar sign and magnitudes. For chains, we note that the magnitude of the (variable) profit coefficients are larger, but marginal effects are of similar magnitude. For example, adding one chain store within 2 miles of an exiting own store reduces mean profits by 11% under ECCP and by 14% under 1-MD, the difference being not statistically significant. If a store is added in the 2-5mi band, mean store profits increase by 9% under ECCP and 14% under 1-MD.⁴⁶

Profits estimates based on the two sets of parameters are of qualitatively similar. To illustrate this point, [Figure A1](#) shows histograms of incumbents' profits (unscaled) based on the baseline and alternative estimation approaches. The magnitude and distribution of profits for single-store firms are comparable across the two specifications. Overall, these results indicate that our baseline estimates of entry costs and profits are robust to the estimation approach providing supporting evidence for our counterfactual exercise.

⁴⁵We do not attempt to calculate and use the optimal weight matrix derived in [Bugni and Bunting \(2021\)](#), given the size of the state space, as it would likely introduce finite-sample bias. We also experimented using the pseudo-likelihood as our objective function, as in [Aguirregabiria and Mira \(2007\)](#), and obtain qualitatively similar results.

⁴⁶In experimenting with the two estimators, we noted that the value function approximation performed better for single-store firms than chains. This is likely due to the fact that the ex-ante value function is simpler for single-store incumbents (since they either stay active or exit); whereas chains have many more choices (remain active, close any of the existing stores, build an additional store in any of the locations, etc.), making it highly non-linear.

Table A1: Estimates of store profits and costs (Baseline ECCP and 1-MD estimators)

Note: Standard errors are obtained via bootstrap of market-histories for both estimation approaches (20 replications). All continuous variables and store counts are in log. Business density is controlled for. Residential rent is at the location level.

C Solution Method for the Dynamic Game

This section provides a detailed overview of the solution method used to find counterfactual equilibria of the dynamic game. The dynamic game is solved via policy iteration (Judd (1998), Rust (2000)). This approach consists in iterating repeatedly between two steps: a given iteration starts by updating the ex-ante and choice-specific value functions given the current vector of CCPs (policy evaluation), then these value functions are used to update the vector CCPs (policy improvement). The algorithm iterates until value functions and CCPs converge, up to a pre-defined tolerance level.

As the state space is extremely large (with continuous state variables), it is computationally prohibitive to solve for value functions and CCPs at all states. We fix the demographic state variables (income, population, etc.) to their value realized in the data and assume their transitions are deterministic. For periods outside of our sample, i.e., $t \geq T + 1$ (where period $T + 1$ corresponds to the year 2020), we assume that these demographic variables become stationary and equal the expected value given their realizations in period T .⁴⁷ We also maintain chains' distribution networks at their state in period T .

The dynamic game is solved by backward induction starting from the first period outside our sample, i.e., $t = T + 1$. In this period we iterate over the following steps:

1. Initialize the vectors of CCPs for each firm and state $\mathbf{P}_{i,T+1}$. If firm i is a potential

⁴⁷To compute this expectation, we assume that demographic variables in each location evolve according to AR-1 processes, where the innovation shocks are allowed to be geographically correlated across locations within a market.

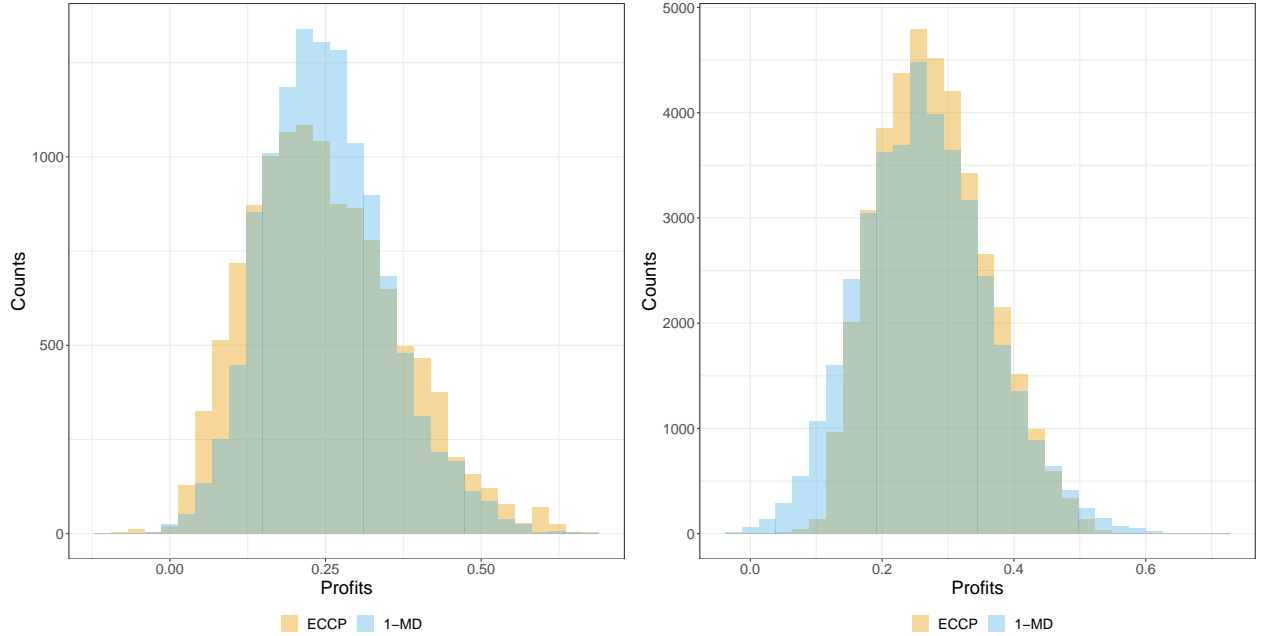

Figure A1: These figures show estimated profits for grocery stores (left) and convenience stores (right) under baseline estimator (ECCP with finite dependence) and the alternative estimator (minimum-distance with value function approximation).

entrant, $\mathbf{P}_{i,T+1}$ is a vector indexed by the state and locations ($\mathcal{M}_{i,j,T+1}, l_+$) giving the CCP of entry into location l in state $\mathcal{M}_{i,j,T+1}$.⁴⁸ If i is an incumbent, $\mathbf{P}_{i,T+1}$ is a vector indexed by ($\mathcal{M}_{i,j,T+1}, a_{it}$) giving the CCP of choosing action a_{it} (remaining active for single-store firms, or building an additional store/remaining active/closing an existing store for chains) in state $\mathcal{M}_{i,j,T+1}$.

2. Form the transition matrix from state $\mathcal{M}_{i,j,T+1}$ to state $\mathcal{M}_{i,k,T+2}$ for each firm type, *conditional* on the action played a . Denote this transition matrix $\mathbf{F}_{i,T+1}(a)$. If firm i plays a terminal action (e.g, an incumbent single-store firm exits) the continuation value is zero, therefore, knowledge of this transition matrix is not necessary.
3. Update the conditional choice-specific value function, leveraging finite dependence. Let $\mathbf{v}_{i,T+1}(a)$ denote a vector collecting the choice-specific value function of firm i if it plays action a for all states ($\mathcal{M}_{i,j,T+1}$). This vector satisfies the equality (in matrix form)

$$\mathbf{v}_{i,T+1}(a) = \boldsymbol{\pi}_{i,T+1}(a) + \beta \mathbf{F}_{i,T+1}(a) [\mathbf{v}_{i,T+1}(\text{exit}) + \gamma - \ln(\mathbf{P}_{i,T+1}(\text{exit}))] \quad (54)$$

where $\boldsymbol{\pi}_i(a)$ is a vector giving single-period profits. For instance, if i is a potential entrant and $a = l_+$, then $\boldsymbol{\pi}_i(l_+) = -\theta_i^{EC}$. $\mathbf{v}_{i,\text{exit}}$ is only a function of the single-period payoff.

⁴⁸Demographic variables are fixed, therefore, different states correspond to different realizations of the spatial market structure (number of stores by type in each location).

4. Update the vectors of CCPs as

$$\mathbf{P}'_{i,T+1}(a) = \frac{\exp(\mathbf{v}_{i,T+1}(a))}{\sum_{\tilde{a}} \exp(\mathbf{v}_{i,T+1}(\tilde{a}))} \quad (55)$$

If the maximum absolute difference between \mathbf{P}_{T+1} and \mathbf{P}'_{T+1} is less than the pre-defined tolerance level, the procedure stops and \mathbf{P}'_{T+1} is saved. If not, define updated CCPs as a convex combination of old and new CCPs $\alpha\mathbf{P}_{i,T+1} + (1 - \alpha)\mathbf{P}'_{i,T+1}$ for each player i and return to Step 2.

This iterative approach yields the equilibrium CCPs for periods $t \geq T + 1$, denoted \mathbf{P}^*_{T+1} . Proceeding backwards, the equilibrium CCPs in period t , given optimal CCPs in period $t + 1$ (\mathbf{P}^*_{t+1}) are obtained by iterating over Steps 2 to 4 above, with the exception that Equation (54) is replaced by

$$\mathbf{v}_{i,t}(a) = \boldsymbol{\pi}_{i,t}(a) + \beta\mathbf{F}_{i,t}(a)[\mathbf{v}_{i,t+1}(exit) + \gamma - \ln(\mathbf{P}^*_{i,t+1}(exit))] \quad (56)$$

where equilibrium CCPs in $t + 1$ are used. As markets are independent, we solve the model for each market separately. For our counterfactual analysis, we initialize this algorithm at a large number of starting values and iterate to a fixed point. We found no evidence of multiple equilibria in the counterfactual exercise.

D Robustness Checks

This section investigates how the various assumptions required by the model impact the quantified effects.

Discount factor. The main estimates use an annual discount factor β equal to 0.9025 (corresponding to 0.95 per 6 months). We examine how the estimation and counterfactual predictions change with different discount factors ranging from 0.85 to 0.95. All else equal, a lower discount factor will be offset with higher estimates of per-period profits, holding entry costs fixed. As expected, we find that estimated mean store profits (conditional on remaining active) are 32% higher with a 0.85 annual discount rate compared to the baseline (0.9025), and 25% lower with a 0.95 annual discount rate.

The counterfactual results remain qualitatively similar albeit the magnitudes depend on the discount factor: for instance, if dollar store chains were prevented from expanding starting in 2010, the increase in the number of independent stores (per market) ranges from 42% to 76% for grocery stores, and from 37% to 71% from convenience stores.⁴⁹

Number of potential entrants. The set of potential entrants is an important modelling choice in entry games. In our setting, there are two types of entrants: the three dollar store chains are “global” entrants, i.e., they are potential entrant in every independent market, and their identity is known. Independent grocery and convenience stores are “local” entrants: each firm considers entry only in a single independent market. Moreover, we observe entry

⁴⁹For computational reasons, counterfactual simulations conducted under alternative discount factors were obtained for markets with one and two locations only.

decisions only by local entrants which end up entering but not by those firms staying out. In the baseline specification, we set the number of “local” potential entrants (by retail format) to the total number of unique stores which have operated at any point in a given market over the period 2008-2019. This is arguably a lower bound on the set of local potential entrants.

We consider how increasing the set of potential entrants affects our structural estimates. The baseline number of local potential entrants (grocery/combination and convenience stores) is increased from the baseline to twice as many as in the baseline. One would expect that, with more local entrants, the model rationalizes observed entry rates (i.e., the number of incumbents) with higher entry costs. This is indeed the case: we find that doubling the number of local potential entrants yields entry costs that are 19% higher for grocery/combination stores and 20% higher for convenience stores relative to the baseline specification. Store profits remain stable across specifications of the number of potential entrants.

E Supplementary Tables and Figures

Figure A2: The effects of dollar store entry at the 0-2mi and 2-5mi bands on spending on the number of independent groceries. Results are from an event study analysis on the balanced panel, using a TWFE and heterogeneity-robust estimators proposed by [Borusyak et al. \(2021\)](#), [Sun and Abraham \(2021\)](#), and [Callaway and Sant’Anna \(2021\)](#). For the latter paper, confidence bands show the uniform sup-t confidence intervals adjusted for multiple hypothesis testing.

Figure A3: The effects of dollar store entry at the 0-2mi and 2-5mi bands on spending on fresh produce. Results are from an event study analysis on the balanced panel, using a TWFE and heterogeneity-robust estimators proposed by [Borusyak et al. \(2021\)](#), [Sun and Abraham \(2021\)](#), and [Callaway and Sant'Anna \(2021\)](#). For the latter paper, confidence bands show the uniform sup-t confidence intervals adjusted for multiple hypothesis testing.

Table A2: Household Spending by Retail Channel and Food Category in Circana Consumer Network (in \$ per year)

Variable	Mean	Median	Std.Dev
Aggregate Spending	2,908.3	2,560.4	1,753.1
Spending in Grocery Channel	1,765.8	1,456.4	1,422.7
Spending on Fresh Produce	88.6	52.7	112.7

Adjusted R^2	0.98	0.59	0.84
Mean Pre-Entry	2.71	2.71	2.71

Notes: Unit of observation is the location-year. Standard errors (in parenthesis) clustered at the location level. Controls for time-varying local demographics (income, population, residential rents, and the one-year percent change in each) are included. Business density is defined as the maximum number of establishments simultaneously operating in location l over the period 2008-2019.

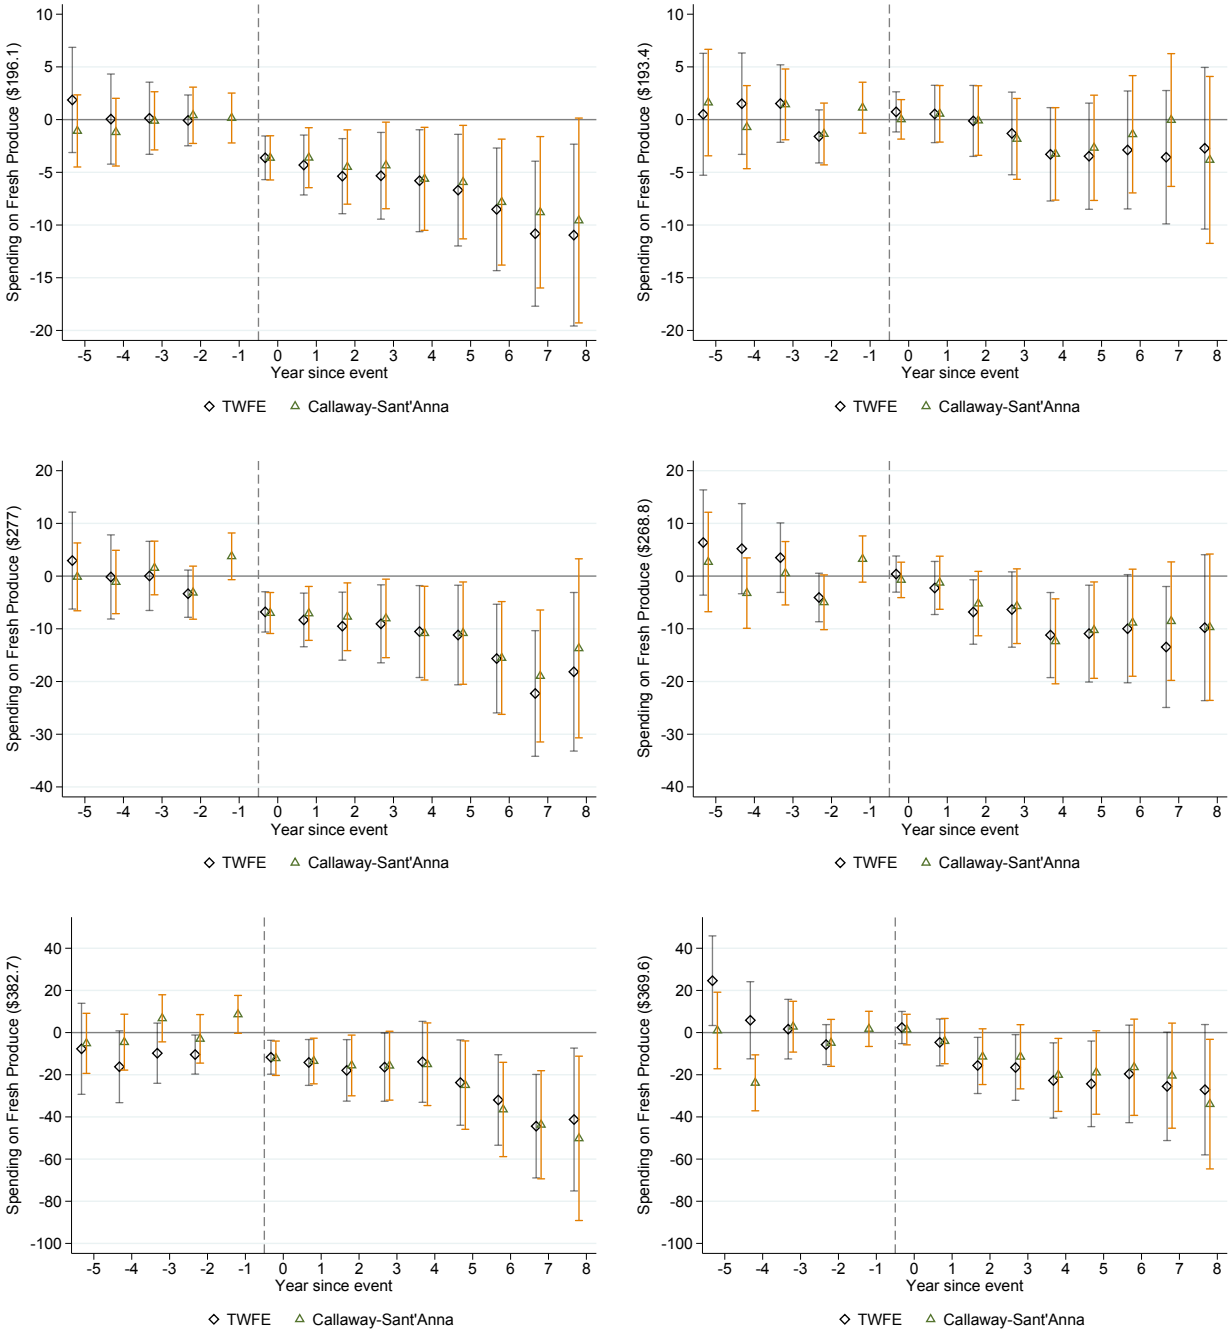

Figure A4: The effects of dollar store entry at the 0-2mi (left panels) and 2-5mi (right panels) bands around the household on fresh produce spending. Results are from an event study analysis on the balanced panel for households who reported spending for at least 10 (top panels), 20 (middle panels), and 30 (bottom panels) weeks per year. Estimates use a TWFE and a heterogeneity-robust estimator proposed by Callaway and Sant'Anna (2021). Household and year fixed effects are included. Confidence bands show the uniform sup-t confidence intervals adjusted for multiple hypothesis testing.

Figure A5: Distribution centers

(a) Number of distribution centers over time (b) Market to nearest distribution center distance

Figure A6: Distribution center locations in 2019

Note: Standard errors are clustered by market. The baseline alternative is "firm is inactive" (either by exiting or staying out). Dollar figures are in 2010\$. Business density is defined as the maximum number of establishments simultaneously operating in location l over the period 2008-2019. Distance to distribution center is at the market level, residential rent is at the location level. All continuous variables and store counts are in log.

<i>By share of population under poverty line</i>								
Below median (0.16)	0.351	0.529	0.178	0.282	0.646	0.927	0.281	0.381
Above median (0.16)	0.471	0.733	0.262	0.365	0.95	1.341	0.391	0.369
<i>By presence of dollar stores in 2010</i>								
No dollar stores in 2010	0.292	0.409	0.117	0.195	0.63	0.852	0.223	0.307
Dollar stores present in 2010	0.564	0.917	0.353	0.488	1.014	1.496	0.483	0.463
<i>By presence of supermarkets in 2010</i>								
No supermarkets in 2010	0.576	0.859	0.283	0.316	0.816	1.171	0.355	0.433
Supermarkets present in 2010	0.406	0.624	0.218	0.323	0.797	1.133	0.336	0.374

Note: Factual corresponds to the expected number of stores under the market equilibrium. CF corresponds to the counterfactual expected number of stores. Δ (resp. % Δ) gives the difference (resp. percentage difference) between the market outcome and counterfactuals averaged over all the locations. All demographic variables and store counts are at the location level, except for the presence of supermarkets which is at the census place (or market) level.
